Transition from phase to generalized synchronization in
time-delay systems

Abstract

The notion of phase synchronization in time-delay systems, exhibiting highly non-phase-coherent attractors, has not been realized yet even though it has been well studied in chaotic dynamical systems without delay. We report the identification of phase synchronization in coupled nonidentical piece-wise linear and in coupled Mackey-Glass time-delay systems with highly non-phase-coherent regimes. We show that there is a transition from non-synchronized behavior to phase and then to generalized synchronization as a function of coupling strength. We have introduced a transformation to capture the phase of the non-phase coherent attractors, which works equally well for both the time-delay systems. The instantaneous phases of the above coupled systems calculated from the transformed attractors satisfy both the phase and mean frequency locking conditions. These transitions are also characterized in terms of recurrence based indices, namely generalized autocorrelation function $P(t)$, correlation of probability of recurrence (CPR), joint probability of recurrence (JPR) and similarity of probability of recurrence (SPR). We have quantified the different synchronization regimes in terms of these indices. The existence of phase synchronization is also characterized by typical transitions in the Lyapunov exponents of the coupled time-delay systems.

PACS numbers: 05.45.Xt, 05.45.Pq
Synchronization of chaotic oscillations is one of the most fundamental phenomena exhibited by coupled chaotic oscillators. Since the identification of chaotic synchronization in identical systems, several different kinds of synchronizations such as generalized, phase, lag, anticipatory and intermittent synchronizations have been identified and demonstrated. Among them chaotic phase synchronization (CPS) plays a crucial role in understanding a large class of weakly interacting nonlinear dynamical systems. Even though the notion of CPS has been well studied in several low-dimensional chaotic dynamical systems during the past decade, CPS in time-delay systems (which are effectively infinite-dimensional) has not yet been identified and reported. A main problem here is to define even the notion of phase itself due to the presence of intrinsic multiple characteristic time scales of the chaotic attractors. Time-delay systems often exhibit complicated non-phase-coherent attractors (which do not have proper rotation around a fixed reference point) with many positive Lyapunov exponents. Hence, the conventional techniques available in the literature to define phase and to identify CPS cannot be used in the case of time-delay systems. In order to overcome this difficulty, we have introduced a nonlinear transformation which transforms the non-phase-coherent chaotic/hyperchaotic attractors of specific time-delay systems into phase-coherent attractors. The transformed attractors allow for the use of conventional methods to identify phase and CPS in time-delay systems. We have also confirmed the onset of phase and the transition from desynchronized state to phase synchronization and its subsequent transition to generalized synchronization as a function of coupling strength using recurrence based indices. These results are also corroborated by the changes in the Lyapunov exponents of the coupled time-delay systems.

I. INTRODUCTION

Synchronization of chaotic oscillations is a fundamental nonlinear phenomenon observed in diverse areas of science and technology. Since the first identification of chaotic synchronization, several types of synchronization have been identified and demonstrated both theoretically and experimentally [1, 2, 3, 4]. Complete (or identical) synchronization [5, 6, 7, 8],
generalized synchronization \[9, 10\] and phase synchronization \[11, 12, 13\] are the three main types of synchronization that have been characterized by the difference in the degree of correlation between the interacting chaotic dynamical systems. Among these, chaotic phase synchronization (CPS) has become the focus of recent research as it plays a crucial role in understanding the behavior of a large class of weakly interacting dynamical systems in diverse natural systems including circadian rhythm, cardio-respiratory systems, neural oscillators, population dynamics, etc \[1, 2, 4\]. Definition of CPS is a direct extension of the classical definition of synchronization of periodic oscillations and can be referred to as entrainment between the phases of interacting chaotic systems, while the amplitudes remain chaotic and, in general, non-correlated \[14\] (see also Appendix A).

The notion of CPS has been investigated so far in oscillators driven by external periodic force \[15, 16\], chaotic oscillators with different natural frequencies and/or with parameter mismatches \[11, 17, 18, 19\], arrays of coupled chaotic oscillators \[14, 20\] and also in essentially different chaotic systems \[21, 22\]. In addition CPS has also been demonstrated experimentally in various systems, such as electrical circuits \[21, 23, 24, 25\], lasers \[26, 27\], fluids \[28\], biological systems \[29, 30\], climatology \[31\], etc. On the other hand CPS in nonlinear time-delay systems, which form an important class of dynamical systems, have not yet been identified and addressed. A main problem here is to define even the notion of phase in time-delay systems due to the intrinsic multiple characteristic time scales in these systems. Studying CPS in such chaotic time-delay systems is of considerable importance in many fields, as in understanding the behavior of nerve cells (neuroscience), where memory effects play a prominent role, in physiological studies, in ecology, in lasers, etc \[1, 2, 4, 32, 33, 34, 35, 36\].

While studying CPS, one usually encounters with the terminologies phase-coherent and non-phase-coherent chaotic attractors. If the flow of a dynamical system has a proper rotation around a fixed reference point, then the corresponding attractor is termed as phase-coherent attractor. In contrast, if the flow does not have a proper rotation around a fixed reference point then the corresponding attractor is called as non-phase-coherent attractor. (More discussion on the distinction between the phase-coherent and non-phase-coherent chaotic attractors along with an illustration is given below in Appendix A). While methods have been well established in the literature to identify phase and to study CPS in phase-coherent chaotic attractors (see again Appendix A), methods to identify phase of non-phase-
coherent chaotic attractors have not yet been well established. Even the most promising approach based on the idea of curvature to calculate the phase of non-phase-coherent attractors is limited to low-dimensional systems and unfortunately methods to identify phase and to study CPS in time-delay systems which often possess highly complicated hyperchaotic attractors have not yet been identified and reported.

Recently, we have pointed out briefly the identification of CPS in unidirectionally coupled nonidentical time-delay systems exhibiting hyperchaos with highly non-phase-coherent attractors [37]. In this paper we present our detailed results on the identification and existence of CPS in coupled piecewise-linear time-delay systems and in coupled Mackey-Glass time-delay systems with parameter mismatches. We will show the entrainment of phases of the coupled systems from asynchronous state and its subsequent transition to generalized synchronization (GS) as a function of coupling strength. Phases of these time-delay systems are calculated using the Poincaré method after a newly introduced transformation of the corresponding attractors, which transforms the original non-phase-coherent attractors of both the systems into smeared limit cycle like attractors. Further, the existence of CPS and GS in both the coupled systems are characterized by recently proposed methods based on recurrence quantification analysis and in terms of Lyapunov exponents of the coupled time-delay systems. Thus, the main results of our paper are

1. Suitable nonlinear transformation involving delay time can be introduced which transforms a chaotic/hyperchaotic non-phase-coherent attractor to a phase-coherent attractor. Then it is easier to find the onset of CPS, GS, etc. using these transformed phase-coherent attractors.

2. Recurrence based indices can be directly used to identify phase, CPS, GS from the original non-phase-coherent chaotic/hyperchaotic attractors.

3. Lyapunov exponents also work as a good guide for the synchronization transitions involving chaotic/hyperchaotic non-phase-coherent attractors.

The plan of the paper is as follows. In Sec. II, a brief discussion about the concept of CPS (the possibility of estimation of the phase in chaotic systems is presented in detail in Appendix [A]) and details of the time-delay systems, namely, piece-wise linear time-delay system and Mackey-Glass system under investigation are presented. In Sec. III, we point
out the existence of CPS and GS in unidirectionally coupled piecewise-linear time-delay systems using the Poincaré section technique (after the introduced transformation), recurrence quantification analysis and Lyapunov exponents of the coupled systems. We will also discuss the existence of CPS and GS in unidirectionally coupled Mackey-Glass time-delay systems in Sec. IV, using the above three different approaches. Finally in Sec. V, we summarize our results.

II. CPS AND TIME-DELAY SYSTEMS

CPS has been studied extensively during the last decade in various nonlinear dynamical systems as discussed in the introduction. However, only a few methods have been available in the literature [1, 4] (for more details see Appendix A) to calculate the phase of chaotic attractors but unfortunately some of these measures are restricted to phase-coherent chaotic attractors, while the others to non-phase-coherent chaotic attractors of low-dimensional systems. It is to be noted that these conventional methods available so far in the literature (as discussed briefly in the Appendix A) to identify phase of the phase-coherent/non-phase-coherent attractors cannot be used in the case of time-delay systems in general, as such systems will very often exhibit more complicated attractors with more than one positive Lyapunov exponents. Correspondingly methods to calculate the phase of non-phase-coherent hyperchaotic attractors of time-delay systems are not readily available. The most promising approach available in the literature to calculate the phase of non-phase-coherent attractors is based on the concept of curvature [38], but this is often restricted to low-dimensional systems. However, we find that this procedure does not work in the case of nonlinear time-delay systems in general, where very often the attractor is non-phase-coherent and high-dimensional. Hence defining and estimating phase from the hyperchaotic attractors of the time-delay systems itself is a challenging task and so specialized techniques/tools have to be identified to introduce the notion of phase in such systems.

It is to be noted that a variety of other nonlinear techniques such as mutual information, recurrence analysis, predictability etc. can be used to identify basic types of synchronization [39]. In particular, mutual information, predictability and their variants have been used for characterizing the existence of complete synchronization, generalized synchronization and the interdependencies among the measured time series of dynamical systems [1, 40, 41, 42].
Mutual information can also be used to measure the degree of PS [43], see also Sec. III A below, provided that phase is already defined. Recently, recurrence based indices are shown to be excellent quantifiers [39] of basic kinds of synchronization including CPS in low dimensional systems and even in the case of noisy, non-stationary data’s. However, as far as we know predictability cannot be used either to define or to identify PS. In any case these measures have not been used so far to identify phase or CPS in time-delay systems.

In order to define/estimate phase and CPS in time-delay systems, in this paper we have introduced three different approaches. Firstly, we have introduced a nonlinear transformation involving time-delay variable that transforms the non-phase-coherent attractors into phase-coherent attractors. After this transformation of the original non-phase-coherent attractor, the transformed attractor allows one to use the conventional techniques. Next, we have used the recently introduced recurrence based indices for the first time in time-delay systems to identify the onset of PS and subsequent transition to GS. Finally, the transition is also confirmed by the changes in the spectrum of Lyapunov exponents of the coupled time-delay system. Further, we find that all these three approaches are in good agreement with the indication of onset of CPS.

As prototypical examples of nonlinear time-delay systems, we consider two specific models, namely, (i) a piece-wise linear time-delay system [44, 45, 46] and (ii) the Mackey-Glass time-delay system [32, 47] and investigate the existence of CPS in the corresponding coupled systems.

A. Piece-wise linear time-delay system

The following scalar first order delay differential equation was introduced by Lu and He [44] and discussed in detail by Thangavel et al. [45],

\[ \dot{x}(t) = -ax(t) + bf(x(t - \tau)) \]  

(1)
where $a$ and $b$ are parameters, $\tau$ is the time-delay and $f$ is an odd piecewise linear function defined as

$$f(x) = \begin{cases} 
0, & x \leq -4/3 \\
-1.5x - 2, & -4/3 < x \leq -0.8 \\
x, & -0.8 < x \leq 0.8 \\
-1.5x + 2, & 0.8 < x \leq 4/3 \\
0, & x > 4/3 
\end{cases} \tag{2}$$

Recently, we have reported [46] that systems of the form (1) exhibit hyperchaotic behavior for suitable parametric values. For our present study, we find that for the choice of the parameters $a = 1.0, b = 1.2$ and $\tau = 15.0$ with the initial condition $x(t) = 0.9, t \in (-15, 0)$, Eq. (1) exhibits hyperchaos. Detailed linear stability analysis, bifurcation analysis and transient effects have been studied in ref. [46]. The corresponding pseudoattractor is shown in the Fig. 1a. The hyperchaotic nature of Eq. (1) is confirmed by the existence of multiple positive Lyapunov exponents. The first ten maximal Lyapunov exponents for the above choice of parameters as a function of delay time $\tau \in (2, 29)$ are shown in Fig. 2a (the spectrum of Lyapunov exponents in this paper are calculated using the procedure suggested by Farmer [47]).

Studying synchronization in coupled systems of the form (1) is particularly appealing because of the facts that (i) system (1) exhibits a hyperchaotic attractor even for very small values of the delay time $\tau$ for appropriate values of the system parameters (the spectrum of Lyapunov exponents as a function of delay time $\tau$ is shown in Fig. 2a) and (ii) it is easily experimentally realizable as the piece-wise linear function can be constructed readily and only low values of delay time are required for construction of a hyperchaotic attractor.

B. Mackey-Glass system

The second model we have used for the investigation of CPS is a model of blood production due to Mackey and Glass [32]. It is represented again by Eq. (1) but with the following functional form for $f(x)$

$$f(x) = x(t - \tau)/(1.0 + x(t - \tau)^{10}). \tag{3}$$
FIG. 1: (a) The non-phase coherent hyperchaotic attractor of the drive (4a) and (b) The non-phase coherent hyperchaotic attractor of the uncoupled response (4b).

Here, \( x(t) \) represents the concentration of blood at time \( t \), when it is produced, and \( x(t - \tau) \) is the concentration when the "request" for more blood is made. In patients with leukemia, the time \( \tau \) may become excessively large, and the concentration of blood will oscillate, or if \( \tau \) is even larger, the concentration can vary chaotically, as demonstrated by Mackey and Glass [32, 47]. This is a prototype model for delay systems exhibiting highly non-phase-coherent chaotic attractors and even hyperchaotic attractors for large value of delay time (\( \tau > 28 \)). The pseudo-chaotic attractor of the Mackey-Glass system (1) and (3) for the standard parameter values \( a = 0.1, b = 0.2 \) and \( \tau = 20 \) with the initial condition \( x(t) = 0.8, t \in (-20, 0) \) is shown in the Fig. 10a in Sec. IV below. The spectrum of Lyapunov exponents as a function of delay time \( \tau \in (14, 37) \) is shown in Fig. 9a (see Sec. IV below).

### III. CPS IN COUPLED PIECEWISE-LINEAR TIME-DELAY SYSTEMS

We first consider the following unidirectionally coupled drive \( x_1(t) \) and response \( x_2(t) \) systems, which we have recently studied in detail in [48, 49],

\[
\begin{align*}
\dot{x}_1(t) &= -ax_1(t) + b_1 f(x_1(t - \tau)), \\
\dot{x}_2(t) &= -ax_2(t) + b_2 f(x_2(t - \tau)) + b_3 f(x_1(t - \tau)),
\end{align*}
\]

(4a) \hspace{1cm} (4b)

where \( b_1, b_2 \) and \( b_3 \) are constants, \( a > 0 \), \( \tau \) is the delay time and \( f(x) \) is the piece-wise linear function of the form \( \text{[2]} \).
We have chosen the values of parameters as (same values as studied in ref. [37]) \( a = 1.0, b_1 = 1.2, b_2 = 1.1 \) and \( \tau = 15 \). For this parametric choice, in the absence of coupling, the drive \( x_1(t) \) and the response \( x_2(t) \) systems evolve independently. Further in this case, both the drive \( x_1(t) \) and the response \( x_2(t) \) systems exhibit hyperchaotic attractors with five positive Lyapunov exponents and four positive Lyapunov exponents, respectively, i.e. both subsystems are qualitatively different (due to \( b_1 \neq b_2 \)). The corresponding attractors are shown in Figs. 1a and 1b, respectively, which clearly show the non-phase-coherent nature. The Kaplan and Yorke [47, 50] dimension for the above attractors turn out to be 8.40 and 7.01, respectively, obtained by using the formula

\[
D_L = j + \frac{\sum_{i=1}^{j} \lambda_i}{|\lambda_{j+1}|},
\]

where \( j \) is the largest integer for which \( \lambda_1 + \ldots + \lambda_j \geq 0 \). The parameter \( b_3 \) is the coupling strength of the unidirectional nonlinear coupling (4b), while the parameters \( b_1 \) and \( b_2 \) play the role of parameter mismatch resulting in nonidentical coupled time-delay systems. The spectrum of the first ten largest Lyapunov exponents of the uncoupled system (4a) for the values of the parameters \( a = 1.0 \) and \( b_1 = 1.2 \) in the range of time-delay \( \tau \in (2, 29) \) is shown in Fig. 2a and that of the system (4b) for the parameter value \( b_2 = 1.1 \) in the same range of delay time is also shown in Fig. 2b.

Now the task is to identify and to characterize the existence of CPS in the coupled time-delay systems (4), possessing highly non-phase-coherent hyperchaotic attractors, when the coupling is introduced \( (b_3 > 0) \). In the following we present three different approaches to study CPS in coupled piecewise-linear time-delay systems (4).

### A. CPS from Poincaré section of the transformed attractor (Fig. 3b)

We introduce a transformation to successfully capture the phase in the present problem. It transforms the non-phase coherent attractor (Fig. 3a) into a smeared limit cycle-like form with well-defined rotations around one center (Fig. 3b). This transformation is performed by introducing the new state variable

\[
z(t + \tau) = z(t + \tau, \hat{\tau}) = x_1(t)x_1(t + \hat{\tau})/x_1(t + \tau),
\]

where \( \hat{\tau} \) is the optimal value of delay time to be chosen (so as to rescale the original non-phase coherent attractor into a smeared limit cycle-like form), and then we plot the above attractor.
FIG. 2: The first ten maximal Lyapunov exponents $\lambda_{\text{max}}$ of (a) the scalar time-delay system (1) and (2) or (4a) for the parameter values $a = 1.0, b_1 = 1.2, \tau \in (2, 29)$ and (b) the scalar time-delay system (4b) for the parameter values $a = 1.0, b_1 = 1.1$ in the same range of delay time in the absence of the coupling $b_3$. 
FIG. 3: (a) The non-phase coherent hyperchaotic attractor of the uncoupled drive $(4a)$ and (b) Transformed attractor in the $x_1(t + \tau)$ and $z(t + \tau)$ space. Here the Poincaré points are represented as open circles.

(Fig. 3a) in the $(x_1(t + \tau), z(t + \tau))$ phase space. The functional form of this transformation (along with a delay time $\hat{\tau}$) has been identified by generalizing the transformation used in the case of chaotic attractors in the Lorenz system [4], so as to unfold the original non-phase-coherent attractor (Fig. 3a) into a phase-coherent attractor. We find the optimal value of $\hat{\tau}$ for the attractor (Fig. 3a) of the piecewise linear time-delay system to be 1.6. It is to be noted that on closer examination of the transformed attractor (Fig. 3b) in the vicinity of the common center, it does not have any closed loop (unlike the case of the original attractor (Fig. 3a)) even though the trajectories show sharp turns in some regime of the phase space. If it is so, such closed loops will lead to phase mismatch, and one cannot obtain exact matching of phases of both the drive and response systems as shown in Fig. 4 and discussed below. Now the attractor (Fig. 3b) looks indeed like a smeared limit cycle with nearly well defined rotations around a fixed center.

It is to be noted that the above transformation (6) can be applied to the non-phase-coherent attractors of any time-delay system in general, except for the fact that the optimal value of $\hat{\tau}$ should be chosen for each system appropriately through trial and error by requiring the geometrical structure of the transformed attractor to have a fixed center of rotation. We have adopted here a geometric approach for the selection of $\hat{\tau}$ and look for an optimum transform which leads to a phase-coherent structure. This is indeed demonstrated for the
attractor of Mackey-Glass system in the next section. The motivation behind this transformation has came from the transformation (A6) which is well known in the case of Lorenz attractor discussed in the Appendix A. The main point that we want to stress here is that even for highly non-phase-coherent hyperchaotic attractors of time-delay systems, there is every possibility to identify suitable transformations of the type (6) to unfold the attractor and to identify phase as demonstrated in the above two typical cases of time-delay systems. One may ask a pertinent question here as to whether there exists a deeper underlying mathematical structure regarding such a transform. We do not have an answer to this question at present and this remains an open problem.

Therefore, the phase of the transformed attractor can be now defined based on an appropriate Poincaré section which is transversally crossed by all trajectories using Eq. (A4) given in Appendix A. Open circles in Fig. 3b correspond to the Poincaré points of the smeared
limit-cycle-like attractor. Phases, \( \phi_1(t) \) and \( \phi_2(t) \), of the drive \( x_1(t) \) and the response \( x_2(t) \) systems, respectively, are calculated from the state variables \( z_1(t + \tau) \) and \( z_2(t + \tau) \) according to Eq. (6). The existence of 1:1 CPS between the systems (4) is characterized by the phase locking condition

\[ |\phi_1(t) - \phi_2(t)| < \text{const.} \tag{7} \]

The phase differences (\( \Delta \phi = \phi_1(t) - \phi_2(t) \)) between the systems (4a) and (4b) are shown in Fig. 4 for different values of the coupling strength \( b_3 \). The phase difference \( \Delta \phi \) between the systems (4a) and (4b) for \( b_3 = 0.0 \) (uncoupled) increases monotonically as a function of time confirming that both systems are in an asynchronous state (also nonidentical) in the absence of coupling between them. For the values of \( b_3 = 1.0 \) and 1.3, the phase slips in the corresponding phase difference \( \Delta \phi \) show that the systems are in a transition state. The strong boundedness of the phase difference specified by Eq. (7) is obtained for \( b_3 > 1.382 \) and it becomes zero for the value of the coupling strength \( b_3 = 1.5 \), showing a high quality CPS.

The mean frequency of the chaotic oscillations is defined as \[ \Omega_{1,2} = \langle d\phi_{1,2}/dt \rangle = \lim_{T \to \infty} \frac{1}{T} \int_0^T \dot{\phi}_{1,2}(t) dt, \tag{8} \]
and the 1:1 CPS between the drive \( x_1(t) \) and the response \( x_2(t) \) systems can also be characterized by a weaker condition of frequency locking, that is, the equality of their mean frequencies \( \Omega_1 = \Omega_2 \). The mean frequency ratio \( \Omega_2/\Omega_1 \) and its difference \( \Delta \Omega = \Omega_2 - \Omega_1 \) are shown in Fig. 5a as a function of the coupling strength \( b_3 \in (0, 3) \). It is also evident from this figure that the mean frequency locking criterion (8) is satisfied for \( b_3 > 1.382 \) from which both the frequency ratio \( \Omega_2/\Omega_1 \) and their difference \( \Delta \Omega \) show substantial saturation in their values confirming the strong boundedness in the phases of both the systems.

The above results can be further strengthened by measuring the degree of PS quantitatively through the concept mutual information between the cyclic phases \[ M = \sum_{i,j} p(i, j) ln \frac{p(i, j)}{p_1(i)p_2(j)}, \tag{9} \]
where \( p_1(i) \) and \( p_2(j) \) are the probabilities when the phases \( \phi_1 \) and \( \phi_2 \) are in the \( i \)th and \( j \)th bins, respectively, and \( p(i, j) \) is the joint probability that \( \phi_1 \) is in the \( i \)th bin and \( \phi_2 \) in the \( j \)th bin. However, it is to be noted that mutual information between the phases can be
used only to characterize the degree of PS provided phase has already been defined/known. Hence mutual information can be used only as an additional quantifier for measuring the degree of phase synchronization. Mutual information $M$ as a function of coupling strength $b_3 \in (0, 3)$ is shown in Fig. 5b, which clearly indicates the high degree of PS for $b_3 > 1.382$ in good agreement with the frequency ratio $\Omega_2/\Omega_1$ and their difference $\Delta\Omega$ shown in Fig. 5a.

B. CPS from recurrence quantification analysis

The complex synchronization phenomena in the coupled time-delay systems (4) can also be analyzed by means of the very recently proposed methods based on recurrence plots [39, 51]. These methods help to identify and quantify CPS (particularly in non-phase coherent attractors) and GS.

For this purpose, the generalized autocorrelation function $P(t)$ has been introduced in [39, 51] as

$$P(t) = \frac{1}{N - t} \sum_{i=1}^{N-t} \Theta(\epsilon - ||X_i - X_{i+t}||), \quad (10)$$

where $\Theta$ is the Heaviside function, $X_i$ is the $i$th data corresponding to either the drive variable $x_1$ or the response variable $x_2$ specified by Eqs. (4) and $\epsilon$ is a predefined threshold. $||.||$ is the Euclidean norm and $N$ is the number of data points. $P(t)$ can be considered as a statistical measure about how often $\phi$ has increased by $2\pi$ or multiples of $2\pi$ within the time $t$ in the original space. If two systems are in CPS, their phases increase on average by $K\cdot2\pi$, where $K$ is a natural number, within the same time interval $t$. The value of $K$ corresponds to the number of cycles when $||X(t + T) - X(t)|| \sim 0$, or equivalently when $||X(t+T)-X(t)|| < \epsilon$, where $T$ is the period of the system. Hence, looking at the coincidence of the positions of the maxima of $P(t)$ for both systems, one can qualitatively identify CPS.

A criterion to quantify CPS is the cross correlation coefficient between the drive, $P_1(t)$, and the response, $P_2(t)$, which can be defined as Correlation of Probability of Recurrence (CPR)

$$CPR = \langle \bar{P}_1(t)\bar{P}_2(t) \rangle / \sigma_1\sigma_2, \quad (11)$$

where $\bar{P}_{1,2}$ means that the mean value has been subtracted and $\sigma_{1,2}$ are the standard deviations of $P_1(t)$ and $P_2(t)$ respectively. If both systems are in CPS, the probability of
recurrence is maximal at the same time \( t \) and CPR \( \approx 1 \). If they are not in CPS, the maxima do not occur simultaneously and hence one can expect a drift in both the probability of recurrences and low values of CPR.

When the systems [41] are in generalized synchronization, two close states in the phase space of the drive variable correspond to that of the response. Hence the neighborhood identity is preserved in phase space. Since the recurrence plots are nothing but a record of the neighborhood of each point in the phase space, one can expect that their respective recurrence plots are almost identical. Based on these facts two indices are defined to quantify GS.

First, the authors of [51] proposed the Joint Probability of Recurrences (JPR),

\[
JPR = \frac{1}{N^2 \sum_{i,j} \Theta(\epsilon_x - ||X_i - X_j||)\Theta(\epsilon_y - ||Y_i - Y_j||) - RR}{1 - RR}
\]

(12)

where \( RR \) is rate of recurrence, \( \epsilon_x \) and \( \epsilon_y \) are thresholds corresponding to the drive and response systems respectively and \( X_i \) is the \( i \)th data corresponding to the drive variable \( x_1 \) and \( Y_i \) is the \( i \)th data corresponding to the response variable \( x_2 \) specified by Eqs. (4). RR measures the density of recurrence points and it is fixed as 0.02 [51]. JPR is close to 1 for systems in GS and is small when they are not in GS. The second index depends on the coincidence of the probability of recurrence, which is defined as Similarity of Probability of Recurrence (SPR),

\[
SPR = 1 - \langle (\bar{P}_1(t) - \bar{P}_2(t))^2 \rangle / \sigma_1 \sigma_2.
\]

(13)

SPR is of order 1 if both systems are in GS and approximately zero or negative if they evolve independently.

Now, we will apply these concepts to the original (non-transformed) attractor (Fig. 3a). We estimate these recurrence based measures from 5000 data points after sufficient transients with the integration step \( h = 0.01 \) and sampling rate \( \Delta t = 100 \). The generalized autocorrelation functions \( P_1(t) \) and \( P_2(t) \) (Fig. 6a) for the coupling \( b_3 = 0.6 \) show that the maxima of both systems do not occur simultaneously and there exists a drift between them, so there is no synchronization at all. This is also reflected in the rather low value of CPR = 0.381. For \( b_3 \in (0.78, 1.381) \), from Fig. 7 we observe the first substantial increase of recurrence reaching CPR \( \approx 0.5 - 0.6 \). Looking into the details of the generalized correlation functions \( P(t) \), we find that now the main oscillatory dynamics becomes locked, i.e. the
main maxima of $P_1$ and $P_2$ coincide. For $b_3 \in (1.382, 2.2)$ CPR reaches almost 1 as seen in Fig. 7 while now the positions of all maxima of $P_1$ and $P_2$ are also in agreement and this is in accordance with strongly bounded nature of phase differences. This is a strong indication for CPS. Note, however that the heights of the peaks are clearly different (Fig. 6b). The differences in the peak heights indicate that there is no strong interrelation in the amplitudes. Further increase of the coupling (here $b_3 = 2.21$) leads to the coincidence of both the positions and the heights of the peaks (Fig. 6c) referring to GS in systems (4). This is also confirmed from the maximal values of the indices $JPR = 1$ and $SPR = 1$, which is due to the strong correlation in the amplitudes of both systems. It is clear from the construction of SPR that it measures the similarity between the generalized autocorrelation functions $P_1(t)$ and $P_2(t)$. In the regimes of CPS, as the generalized autocorrelation functions coincide in almost all the regimes except for the height of its maxima, it is also quantified by larger values of SPR. The index SPR in Fig. 7 also shows the onset of CPS and it fluctuates around the value 1 in the regime of CPS ($b_3 \in (1.382, 2.2)$) before reaching saturation confirming the strong correlation in the amplitudes of both the systems, thereby quantifying the existence of GS. The transition from non-synchronized state via CPS to GS is characterized by the maximal values of CPR, SPR and JPR (Fig. 7). As expected from the construction of these functions, CPR refers mainly to the onset of CPS, whereas JPR quantifies clearly the onset of GS and SPR indicates both the onset of CPS and GS. In this connection, we have also confirmed the onset and existence of GS by using the auxiliary system approach [52] introduced by Abarbanel et al for the range of the coupling strength $b_3 > 2.2$.

C. CPS from spectrum of Lyapunov exponents

The transition from non-synchronization to CPS is also characterized by changes in the Lyapunov exponents of the coupled time-delay systems [4]. The spectrum of the eight largest Lyapunov exponents of the coupled systems is shown in Fig. 8. From this figure one can find that all the positive Lyapunov exponents, except the largest one ($\lambda_{\text{max}}^{(2)}$), corresponding to the response system suddenly become negative at the value of the coupling strength $b_3 = 0.78$ which is an indication of the onset of transition regime. One may also note that at this value of $b_3$ already one of the Lyapunov exponents of the response system attains negative saturation while the another one reaches negative saturation slightly above
$b_3 = 0.78$. This is a strong indication that in this rather complex attractor the amplitudes become somewhat interrelated already at the transition to CPS (as in the funnel attractor of the Rössler system). Also the third positive Lyapunov exponent of the response system gradually becomes more negative from $b_3 = 0.78$ and reaches its saturation value at $b_3 = 1.381$ confirming the onset of CPS (which is also indicated by the transition of the indices of CPR and SPR in Fig. 7 in the range of $b_3 \in (0.78, 1.381)$). It is interesting to note that the Lyapunov exponents of the response system $\lambda_i^{(2)}$ (other than $\lambda_{max}^{(2)}$) are changing already at the early stage of CPS ($b_3 \in (0.78, 1.381)$), where the complete CPS is not yet attained. This has also been observed for the onset of CPS in phase-coherent and non-phase-coherent oscillators without time-delay [11, 22, 54].

IV. CPS IN COUPLED MACKEY-GLASS SYSTEMS

In this section, we will bring out the existence of CPS in coupled Mackey-Glass systems of the form

\[
\begin{align*}
\dot{x}_1(t) &= -ax_1(t) + b_1 x_1(t-\tau)/(1.0 + x_1(t-\tau)^{10}), \\
\dot{x}_2(t) &= -ax_2(t) + b_2 x_2(t-\tau)/(1.0 + x_2(t-\tau)^{10}) + b_3 x_1(t-\tau)/(1.0 + x_1(t-\tau)^{10}),
\end{align*}
\]

where $a, b_1, b_2$ are constants, $b_3$ is the coupling parameter, and $\tau$ is the delay time.

We have chosen the parameter values (cf. [32, 47]) as $a = 0.1, b_1 = 0.2, b_2 = 0.205, \tau = 20$ and varied the coupling strength $b_3$. The non-phase-coherent chaotic attractor of the system $x_1(t)$, Eq. (14a), for the above choice of parameters is shown in Fig. 10b and it possesses one positive and one zero Lyapunov exponents. Similarly, the second system $x_2(t)$, Eq. (14b), also exhibits a non-phase-coherent chaotic attractor with one positive and one zero Lyapunov exponents for the chosen parametric values in the absence of the coupling strength $b_3$. The parameters $b_1$ and $b_2$ contribute to the parameter mismatch between the systems $x_1(t)$ and $x_2(t)$. The spectrum of the first four maximal Lyapunov exponents of both systems (14a) and (14b) are shown in Figs. 9a and 9b respectively as a function of delay time $\tau \in (14, 37)$ when $b_3 = 0$. The Kaplan and Yorke [47, 50] dimension calculated using (5) for the present systems ((14a) and (14b)) work out to be 2.27969 and 2.21096, respectively. Now, the existence of CPS as a function of the coupling strength in the coupled Mackey-
Glass systems (14) will be discussed using the above three approaches used for identifying CPS in coupled piecewise-linear time-delay systems (4).

A. CPS from Poincaré section of the transformed attractor (Fig. 10b)

The non-phase-coherent chaotic attractor (Fig. 10a) of the Mackey-Glass system is transformed into a smeared limit cycle-like attractor (Fig. 10b) using the same transformation (6) as used for the piecewise-linear time-delay systems. For the attractor (Fig. 10a) of the Mackey-Glass system, the optimal value of the delay time \( \hat{\tau} \) in Eq. (6) is found to be 8.0. The Poincaré points are shown as open circles in the Fig. 10b from which the instantaneous phase \( \phi_z(t) \) is calculated using (A4). The existence of CPS in the coupled Mackey-Glass systems (14) is also characterized by the phase locking condition (7) as shown in Fig. 11. The phase differences \( \Delta \phi = \phi_z^1(t) - \phi_z^2(t) \) between the systems (14a) and (14b) for the values of the coupling strength \( b_3 = 0.04, 0.08, 0.11, 0.12 \) and 0.3 are shown in Fig. 11. For the value of the coupling strength \( b_3 = 0.3 \), there exists a strong boundedness in the phase difference showing high quality CPS. The mean frequency ratio \( \Omega_2/\Omega_1 \) calculated from (8) along with the mean frequency difference \( \Delta \Omega \) is shown in the Fig. 12a. The value of mean frequency ratio \( \Omega_2/\Omega_1 \approx 1 \) in the range of \( b_3 \in (0.12, 0.23) \) corresponding to the transition regime (which is also to be confirmed from the indices CPR and JPR in the next subsection), see the inset of Fig. 12a. Similarly the mean frequency difference is also \( \Delta \Omega \approx 0 \) confirming the transition regime. For the value of \( b_3 > 0.23 \) both quantities \( \Omega_2/\Omega_1 \) and \( \Delta \Omega \) acquire the complete saturation in their values confirming the existence of CPS. Further, the mutual information calculated using Eq. (9) clearly indicates the increase in the degree of PS for the value of coupling strength \( b_3 > 0.23 \) as shown in Fig. 12b, which is also in agreement with the frequency ratio \( \Omega_2/\Omega_1 \) and the mean frequency difference \( \Delta \Omega \) shown in Fig. 12b.

B. CPS from recurrence quantification analysis

The existence of CPS from the original non-phase-coherent chaotic attractors of the systems (14) is analyzed in this section using the recurrence quantification measures defined in the section II. B. We have estimated these measures again using a set of 5000 data points, and the same integration step and the sampling rate as used in the case of coupled piecewise-
linear time-delay systems \(^4\). The maxima of generalized autocorrelations of both the drive
\(P_1(t)\) and the response \(P_2(t)\) systems (Fig. 13a) do not occur simultaneously for \(b_3 = 0.1\),
which indicates the independent evolution of both the systems without any correlation and
this is also reflected in the rather low value of CPR = 0.4. For \(b_3 = 0.3\), the maxima of
both \(P_1(t)\) and \(P_2(t)\) are in good agreement (Fig. 13b) and this shows the strongly bounded
phase difference. It is to be noted that even though both the maxima coincide, the heights of
the peaks are clearly of different magnitudes contributing to the fact that there is no strong
correlation in the amplitudes of both the systems indicating CPS. Both the positions and the
peaks are in coincidence (Fig. 13c) for the value of coupling strength \(b_3 = 0.9\) in accordance
with the strong correlation in the amplitudes of both the systems \(^14\) corresponding to GS.
This is also reflected in the maximal values of both JPR=1 and SPR=1. The spectra of
CPR, JPR and SPR are shown in Fig. 14. The onset of CPS is shown by the first substantial
increase of the index CPR at \(b_3 = 0.11\) and the transition regime is shown by the successive
plateaus of CPR in the range \(b_3 \in (0.12, 0.23)\). The maximal values of CPR for \(b_3 > 0.23\)
indeed confirm the existence of high quality CPS. The existence of GS is also confirmed
from both the indices JPR and SPR.

C. CPS from spectrum of Lyapunov exponents

The onset of CPS is also characterized by the changes in the spectrum of Lyapunov
exponents of the coupled Mackey-Glass systems \(^14\). The spectrum of the first four largest
Lyapunov exponents of the coupled systems \(^14\) is shown in Fig. 15. The zero Lyapunov
exponent of the response system \(x_2(t)\) already becomes negative as soon as the coupling is
introduced and the onset of CPS is indicated by the negative saturation of the zero Lyapunov
exponent at \(b_3 = 0.11\). The positive Lyapunov exponent of the response system becomes
gradually negative in the transition regime \((b_3 \in (0.12, 0.23))\) and it reaches its negative
saturation at \(b_3 = 0.23\) at which high quality CPS exists. The transition of the positive
Lyapunov exponent to negativity in this rather complex attractor is again a firm indication
of some degree of correlation in the amplitudes of both systems even before the onset of
CPS. As noted earlier, this behaviour of negative transition of positive Lyapunov exponent
of response system before CPS has also been observed in Refs. \(^{11, 22, 54}\).
V. SUMMARY AND CONCLUSION

We have identified and characterized the existence of CPS in both the coupled piecewise-linear time-delay systems and in the coupled Mackey-Glass systems possessing highly non-phase-coherent chaotic attractors. We have shown that there is a typical transition from a non-synchronized state to CPS and subsequently to GS as a function of the coupling strength in both systems. Similar results are obtained for different sampling intervals \( \Delta t \) and for various values of delay time \( \tau \).

We have introduced a suitable transformation, which works equally well for both the systems possessing characteristically distinct attractors (hyperchaotic attractor in piecewise linear time-delay system and chaotic attractor in the Mackey-Glass system), to capture the phase of the underlying non-phase-coherent attractor. Both the phase and the frequency locking criteria are satisfied by the instantaneous phases calculated from the transformed attractors in both the piecewise-linear and the Mackey-Glass time-delay systems. The frequency ratio and its difference as a function of coupling strength clearly shows the onset of CPS in both cases. We have also characterized the existence of CPS and GS in terms of recurrence based indices, namely generalized autocorrelation function \( P(t) \), CPR, JPR and SPR and quantified the different synchronization regimes in terms of them. The onset of CPS and GS are also clearly shown by the spectra of CPR, JPR and SPR. The above transition is also confirmed by the changes in the spectrum of Lyapunov exponents. The recurrence based technique as well as the new transformation are also appropriate for the analysis of experimental data and we are now investigating the experimental verification of these findings in nonlinear electronic circuits and in biological systems. Also the recurrence based indices are found to be more appropriate for identifying the existence and analysis of synchronizations, in particular CPS, and their onset in the case of nonlinear time-delay systems in general, where very often the attractor is non-phase-coherent and high-dimensional. It is also to be emphasized that the recurrence based measures are more efficient than other nonlinear techniques \(^{[39]}\) such as mutual information, predictability, etc. These measures have high potential for applications and we are also investigating the possibility of extending these techniques to complex networks.

APPENDIX A: CPS IN CHAOTIC SYSTEMS: PHASE-COHERENT AND NON-PHASE-COHERENT ATTRACTORS

Definition of CPS in coupled chaotic systems is derived from the classical definition of phase synchronization in periodic oscillators. Interacting chaotic systems are said to be in phase synchronized state when there exists entrainment between phases of the systems, while their amplitudes may remain chaotic and uncorrelated. In other words, CPS exists when their respective frequencies and phases are locked\cite{1, 4, 14}. To study CPS, one has to identify a well defined phase variable in both coupled systems. If the flow of the chaotic oscillators has a proper rotation around a certain reference point, the phase can be defined in a straightforward way. In this case the corresponding attractor is referred to as a phase-coherent attractor in the literature\cite{1, 4, 14, 17, 37, 38, 19} and the phase can be introduced straightforwardly as\cite{1, 4}

\[
\phi(t) = \arctan(y(t)/x(t)).
\] (A1)

A more general approach to define the phase in chaotic oscillators is the analytic signal approach\cite{1, 4} introduced in\cite{55}. The analytic signal \(\chi(t)\) is given by

\[
\chi(t) = s(t) + i\tilde{s}(t) = A(t)\exp^{i\Phi(t)},
\] (A2)

where \(\tilde{s}(t)\) denotes the Hilbert transform of the observed scalar time series \(s(t)\)

\[
\tilde{s}(t) = \frac{1}{\pi} P.V. \int_{-\infty}^{\infty} \frac{s(t')}{t-t'} dt',
\] (A3)

where P.V. stands for the Cauchy principle value of the integral and this method is especially useful for experimental applications\cite{1, 4}.

The phase of a chaotic attractor can also be defined based on an appropriate Poincaré section which the chaotic trajectory crosses once for each rotation. Each crossing of the
orbit with the Poincaré section corresponds to an increment of $2\pi$ of the phase, and the phase in between two crosses is linearly interpolated \[1,4\],

$$\Phi(t) = 2\pi k + 2\pi \frac{t - t_k}{t_{k+1} - t_k}, \quad (t_k < t < t_{k+1})$$ 

where $t_k$ is the time of $k$th crossing of the flow with the Poincaré section. For the phase coherent chaotic oscillators, that is, for flows which have a proper rotation around a certain reference point, the phases calculated by these three different ways are in good agreement \[1,4\].

As a typical example, consider the Rössler system

\begin{align*}
\dot{x} &= -y - z, \\
\dot{y} &= x + ay, \\
\dot{z} &= 0.2 + z(x - 8.5).
\end{align*}

The topology of the attractor of the Rössler system is determined by the parameter $a$. For $a = 0.15$, a phase coherent attractor (see Fig. 16a) is observed with rather simple topological properties \[56,57\], (where the projection of the chaotic attractor on the $(x, y)$ plane looks like a smeared limit cycle with the phase point always rotates around a fixed origin with monotonically increasing phase) and hence the phase can be calculated straightforwardly as discussed above.

However, in chaotic dynamics one often encounters non-phase-coherent attractors where the flows are without a proper rotation around a fixed reference point (with the origin coinciding with the center of rotation), in which case a single characteristic time scale does not exist in general. In such circumstances it is difficult or impossible to find a proper center of rotation and it is also intricate to find a Poincaré section that is crossed transversally by all trajectories of the chaotic attractor. As a consequence such a non-phase-coherent chaotic attractor is not characterized by a monotonically increasing phase. Hence phase of such a non-phase-coherent attractor cannot be defined straightforwardly as in the case of phase-coherent attractor. Therefore the above definitions of phase are no longer applicable for non-phase-coherent chaotic attractors. So specialized techniques/tools have to be identified to introduce phase in non-phase-coherent attractors.

It has also been demonstrated that certain non-phase-coherent chaotic attractors can be transformed into smeared limit-cycle like attractors by introducing a suitable transformation.
of the original variables. For example, in the case of Lorenz attractor, a transformation of the form

$$u(t) = \sqrt{x^2 + y^2}$$  \hspace{1cm} (A6)

is introduced [1] and the projected trajectory in the plane \((u, z)\) resembles that of the Rössler attractor. Now phase of the respective attractor is introduced using the above approaches for phase-coherent attractors.

However, such a transformation does not always exist or can be found in the case of non-phase-coherent attractors in general. Again, as a typical example consider the Rössler system specified by Eq. (A5). The topology of the Rössler attractor changes dramatically if the parameter \(a\) exceeds 0.21 and the phase in this case is not well defined. Funnel (non-phase-coherent) attractor for the value \(a = 0.25\) is shown in Fig. 16b. There are large and small loops (see Fig. 16b) on the \((x, y)\) plane and it is not evident which phase gain should be attributed to these loops and hence phase cannot be calculated simply as in the case of phase-coherent chaotic attractor (Fig. 16a) or through simple transformations. Therefore, recently another definition of the phase based on the general idea of the curvature has been proposed by Osipov et al. [38]. For any two-dimensional curve \(r = (u, v)\) the angle velocity at each point is

$$\nu = \frac{(ds/dt)/R}{(ds/dt)/R},$$

where \(ds/dt = \sqrt{\dot{u}^2 + \dot{v}^2}\) is the speed along the curve and \(R = (\dot{u}^2 + \dot{v}^2)^{3/2}/(\dot{v}\ddot{u} - \ddot{v}\dot{u})\) is the radius of the curvature. If \(R > 0\) at each point, then

$$\nu = \frac{d\Phi}{dt} = \frac{\dot{v}\ddot{u} - \ddot{v}\dot{u}}{\dot{u}^2 + \dot{v}^2}$$

is always positive and hence the variable

$$\Phi = \int \nu dt = \arctan \frac{\dot{v}}{\dot{u}}$$  \hspace{1cm} (A7)

is a monotonically increasing function of time and can be considered as the phase of the oscillator. These definitions of frequency and phase are general for any dynamical system if the projection of the phase trajectory on some plane is a curve with a positive curvature. Now for the non-phase-coherent Rössler attractor in the funnel regime, the projections of chaotic trajectories on the plane \((\dot{x}, y)\) always rotate around the origin, and the phase can be defined
as $\Phi = \arctan(\dot{y}/\dot{x})$ \cite{note1}. However, it is not clear whether an appropriate plane can always be found, on which the projected trajectories rotate around the origin for higher dimensional chaotic systems as such systems will very often exhibit more complicated attractors with more than one positive Lyapunov exponent as in the case of typical time-delay systems discussed in the main part of this paper.
