Short Communication

Energy Supply for Stomatal Opening in Epidermal Strips of Commelina benghalensis

AGEPATI S. RAGHAVENDRA
Centro de Estudios Fotosinteticos y Bioquimicos (CEFOBI), Suipacha 531, 2000 Rosario, Argentina

ABSTRACT

The influence of light or darkness on stomatal opening in epidermal strips of Commelina benghalensis was evaluated in the presence or absence of O₂ and/or metabolic inhibitors. Opening was restricted in nitrogen and was promoted by NADH and acids of the tricarboxylic acid cycle (succinate and α-ketoglutarate) in CO₂-free air in light as well as in darkness. The enhancement by light of stomatal opening was prevalent under nitrogen or in the presence of the respiratory inhibitors (sodium azide and oligomycin). Respiratory inhibitors decreased the opening in light or darkness under CO₂-free air but exhibited no effect under nitrogen, whereas phosphorylation uncoupurers were inhibitory in light or darkness under both CO₂-free air and nitrogen. The results suggest that oxidative phosphorylation is a basic source of energy for stomatal opening, although photophosphorylation could be an energy source.

In spite of considerable effort in studying the physiology of stomata, the mechanism of stomatal opening and closing is not understood clearly (1, 7, 11, 12, 18). It is established that stomatal opening involves an increase in the turgor of guard cells which requires energy (11, 13, 18), but information on the source of energy is rather limited.

The acceleration of stomatal opening by light is a common observation and several investigators proposed that light might supply energy for the opening process, probably through cyclic electron flow (5, 8, 9, 16, 20). But stomata can open to a remarkable extent even in dark and it has therefore been claimed that light does not supply energy to the stomatal mechanism (18). There is morphological evidence that the energy required for stomatal opening could come from oxidative phosphorylation (6, 12, 14, 18), mainly because of the occurrence of numerous mitochondria in guard cells. ADP or ATP has been found to enhance stomatal opening in isolated epidermal strips (4, 6, 16, 17, 19). The experiments reported herein were directed toward delineating more clearly the possible role of oxidative phosphorylation.

MATERIALS AND METHODS

Plant Material. Commelina benghalensis L. plants were grown in seed pans outdoors on soil supplemented with manure (soil-farmyard manure, 3:1). The average temperature was 30 C during day and 20 C night with about a 12-h photoperiod. The plants were watered daily.

Preparation of Epidermal Strips. Second to fourth fully expanded leaves from 6- to 8-week-old plants were picked in the morning (usually between 9:00 and 10:00 AM) and used within 15 min. The lower epidermis was peeled off carefully. The adhering mesophyll cells were removed by rubbing the underside of the strip with a zero-size painting brush. The epidermal strips then were cut into pieces of approximately 5 x 10 mm and were left in distilled H₂O for 2 h in dark at room temperature (28-30 C).

Incubation. The strips were transferred to 2 x 15-cm side-arm test tubes containing 10 ml 25 mM Mes buffer (pH 6.0), 100 mM KCl, 100 μM CaSO₄, 10 mM ADP (unless otherwise specified), and the test chemicals at the given final concentrations. The tubes for similar gaseous treatment were interconnected and the gas (air, CO₂-free air, or N₂) was bubbled at a rate of 300 to 400 ml min⁻¹. The tubes were placed in a water bath maintained at 30 C and were either kept in darkness or illuminated at an irradiance of 100 W m⁻² with a bank of incandescent bulbs.

Measurement. The content of each tube was emptied quickly at given times into a Petri dish. Stomatal apertures were measured with a precalibrated ocular micrometer. Five strips were used for each treatment and 10 stomata, chosen at random, were measured in each strip. The experiments were repeated three times.

Status of Epidermal Strips. The guard cells were living during and after the 5-h experimental period as checked by the uptake of neutral red and protoplasmic streaming.

RESULTS AND DISCUSSION

ADP is included in the incubation medium of these studies presented here because it is one of the substrates for phosphorylation and has amplified the stomatal responses to the gaseous phase in light or darkness. Figure 1 presents the responses of stomata to O₂ and CO₂ in the presence or absence of ADP. With illumination, stomatal opening was maximum in CO₂-free air and minimal under N₂ (Fig. 1A). Stomata did not open in darkness under N₂ (Fig. 1B). In presence of ADP, illumination enhanced stomatal opening in air, CO₂-free air, N₂ (Fig. 1C) compared to that in darkness (Fig. 1D). However, the enhancement by light of opening was maximum in N₂. The stomatal opening was significant even in darkness in presence of ADP under air or CO₂-free air (Fig. 1D).

Apparently ADP can enter guard cells as exhibited by the responses to ADP in the present observations (Fig. 1) as well as by earlier workers (4, 6, 16, 17, 19). Studies with isolated leaf cells also indicate that externally supplied nucleotides and sugar phosphates can modify their metabolism (3, 10).

Succinate and α-ketoglutarate (intermediates of the tricarboxylic acid cycle) and NADH promoted stomatal opening in light and darkness, but only under CO₂-free air (Table 1). They had no
The data of Antimycin A, respiratory inhibitors in control experiments with + ADP and + 10 mM sodium azide in light and darkness, relative to air and CO2-free air, are shown in Table 1. The data represent the stomatal aperture after a 5-hour incubation period.

* Opening at the start of the incubation.

Three points become evident from the experiments on stomatal opening in various gas phases (Fig. 1): (a) illumination is not necessary to drive stomatal movement since opening was observed even in darkness; (b) the involvement of oxidative metabolism is indicated by the restriction of opening in the absence of O2; and (c) light can play a role as suggested by the enhancement of opening in air or N2 upon illumination.

The restriction of stomatal opening by uncouplers of phosphorylation (Table 1) indicates that the process of opening is the result of active ion transport, presumably potassium (1, 7, 18). The extensive work of Pallaghy and Fischer (13) already has provided evidence that the uptake of both 42K and 32Cl requires energy and is sensitive to metabolic inhibitors. At least part of the energy for stomatal opening can come from oxidative phosphorylation as supported by three observations in Table 1: (a) the ability of externally added ATP to increase slightly the opening under N2; (b) the enhancement of opening by NADH and organic acids of the tricarboxylic acid cycle only in CO2-free air; and (c) the suppression of opening by inhibitors of respiratory electron transport chain and oxidative phosphorylation.

Illumination nearly doubled stomatal aperture in air or CO2-free air (Fig. 1); the enhancement was prominent in N2 or in the presence of respiratory inhibitors, like sodium azide or oligomycin. This indicates that photophosphorylation was an energy source. The data indicate that stomatal opening is driven by a common pool of ATP contributed from oxidative phosphorylation and photophosphorylation. Guard cells are characterized by the presence of numerous mitochondria as well as chloroplasts (2, 14, 15) and possess the enzymes of the tricarboxylic acid cycle (18).

Acknowledgments—I wish to thank Dr. R. H. Valleejos, Director, Centro de Estudios Fototinteticos y Bioquimicos, for allowing me to use the facilities. I also thank Professor A. T. Jagendorf for stimulating discussion and Professor T. A. Mansfield for reading the manuscript.
