(Dated: February 6, 2008)

Measurements of Nernst effect, resistivity and Hall angle on epitaxial films of Y$_{1-x}$Pr$_x$Ba$_2$Cu$_3$O$_{7-\delta}$ (Pr-YBCO, 0$\leq$ x $\leq$ 0.4) are reported over a broad range of temperature and magnetic field. While the Hall and resistivity data suggest a broad pseudogap regime in accordance with earlier results, these first measurements of the Nernst effect on Pr-YBCO show a large signal above the superconducting transition temperature ($T_c$). This effect is attributed to vortex-like excitations in the phase incoherent condensate existing above $T_c$. A correlation between disorder and the width of the phase fluctuation regime has been established for the YBCO family of cuprates, which suggests a $T_c$ $\approx$110K for disorder-free YBa$_2$Cu$_3$O$_{7-\delta}$.

The anomalously large Nernst voltage well above the zero-field $T_c$ in hole-doped cuprate superconductors is now a well established experimental observation with a dominant view that it is due to vortex-like excitations in the phase uncorrelated superfluid above $T_c$. Such excitations nucleate in the presence of an external field due to a non-zero pairing amplitude of incoherent phase at $T>T_c$ and drift down the thermal gradient generating a transverse voltage. The appearance of the Nernst signal on approaching $T_c$ from above, therefore, marks the onset of a phase uncorrelated pairing amplitude. The observation of an enhanced diamagnetism near the onset temperature $T_p$ of the anomalous Nernst signal in some hole-doped cuprates strongly supports the vortex-like excitations scenario. The fact that the regime of this large Nernst effect overlaps with the temperature range where a pseudogap is seen in the electronic excitation spectrum, somehow also suggests that the anomalous Nernst effect may be related to the pseudogap phenomenon, although counterviews also exist on the prescription of vortex-like excitations and correlation between Nernst effect and pseudogap phenomenon. Rullier-Albenque et al. have established a correlation between the width of the phase fluctuation regime over which a large Nernst voltage is seen and disorder in the CuO$_2$ planes induced by electron irradiation. The disordered samples show a wider range of phase fluctuations. However, high $T_c$ cuprates can also be subjected to out-of-plane disorder by changing the ionic radius of the rare earth and alkaline earth sites while keeping the hole concentration fixed. The disorder works as a weak scatterer and reduces $T_c$ substantially.

The cuprate Y$_{1-x}$Pr$_x$Ba$_2$Cu$_3$O$_{7-\delta}$ (Pr-YBCO) presents a very interesting system to study the role of out-of-plane disorder on the regime of incoherent phase fluctuations in YBa$_2$Cu$_3$O$_{7-\delta}$ cuprates because the ionic radius of Pr$^{3+}$ is larger by a factor of about 1.134 compared to the ionic radius of Y$^{3+}$. In this paper, we present the first measurements of the normal state Nernst Effect in Y$_{1-x}$Pr$_x$Ba$_2$Cu$_3$O$_{7-\delta}$ over a broad range of composition. These data have been augmented by measurements of Hall angle and in-plane resistivity over a wide range of field and temperature. We note that while the zero-field superconducting transition temperature $T_c$ drops with increasing Pr in a quasi non-linear manner as reported earlier, the fluctuation regime $\Delta T_H$($=T_{Hc}-T_c$) widens. Most remarkably, an interesting correlation emerges between $T_p$ and $T_c$ in the YBCO family of cuprates with in-plane and out-of-plane disorder.

The c-axis oriented epitaxial Y$_{1-x}$Pr$_x$Ba$_2$Cu$_3$O$_{7-\delta}$ ($x$=0, 0.1, 0.2, 0.3, 0.4) films of thickness about 2500 Å were fabricated on (100) SrTiO$_3$ substrates by pulsed laser deposition using a KrF excimer laser($\lambda$=248 nm) with a typical repetition rate and energy density of 5 Hz and 2 J/cm$^2$ respectively, which yields a growth rate of 1.6 Å/second. The deposition temperature and oxygen partial pressure during film deposition were set 800 °C and about 400 mTorr respectively.

The in-plane resistivity and Hall effect measurements were done on the films patterned to a standard Hall bar in a Quantum Design PPMS with a 14 T magnet. The Nernst measurements were performed using a one-heater-two-thermometer technique. The sample was attached on one end to a copper block with a mechanical clamp and the other end was left free. A small chip resistor heater is attached on the free end, and a temperature gradient is created by applying a constant current to the heater. Two tiny Lakeshore Cernox thermometers are attached on the two ends of the sample to monitor the temperature gradient continuously. The Nernst voltage is measured with a Keithly 2001 multimeter with a 1801 preamp while the field is slowly ramped at a rate of 0.3 T/min between -14 T and +14 T($H \perp ab$). The system temperature was well controlled to give stability of the temperature of ±1 mK, which enables us to perform a high
resolution Nernst voltage measurement (typically ~10 nV in our setup). The temperature gradient is around 0.5-
2 K/cm depending on the temperature of measurement, and the sample temperature is taken as the average of hot and cold end temperatures. The Nernst signal is obtained by subtracting negative field data from positive field data to eliminate any possible thermopower contribution. The Nernst signal was defined as

\[ e_y = \frac{E_y}{-\nabla T} \]  

where \( E_y \) is the transverse electrical field across the sample and \(-\nabla T\) is the temperature gradient along its length.

Fig. 1 shows the temperature dependence of in-plane resistivity \( \rho_{ab} \) for \( Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta} \) films with Pr concentration from 0 to 0.4. The zero field superconducting transition temperature \( T_c \), decreases from 90 K for the \( x=0 \) film to about 40 K for the underdoped \( x=0.4 \) film in agreement with published work on these cuprates.\(^2\)\(^,\)\(^10\)\(^,\)\(^11\)\ The in-plane resistivity increases with Pr content, which suggests a decrease of carrier concentration or carrier mobility due to out-of-plane disorder caused by Pr. While the resistivity \( \rho_{ab}(T) \) remains metallic in the normal state, a small upturn in \( \rho_{ab}(T) \) on cooling is seen in the \( x=0.4 \) film just above \( T_c \), which may be due to charge localizations found in many other cuprates. The resistivity has a linear temperature dependence for the fully oxygenated Pr-free film, while it deviates from linearity on increasing the Pr doping. The temperature below which this deviation from linearity sets in is about 190 K in the \( x=0.1 \) film and gradually exceeds 300 K for the film with the highest Pr concentration. This nonlinear \( \rho_{ab} \) below 300 K for the higher Pr-rich samples indicates a pseudogap regime above \( T_c \). This deviation of \( \rho_{ab}(T) \) from linearity on cooling is not monotonic. To illustrate this point we show in the inset of Fig. 1 the temperature derivative \( d\rho_{ab}(T)/dT \) of all the films. The \( d\rho_{ab}(T)/dT \) vs T plot of the films with \( x \geq 0.2 \) goes through a maximum and the peak temperature shifts towards higher values with the increasing Pr content. This observation is consistent with the resistivity data of \( Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta} \) single crystals.\(^2\) We note that the peak temperature \( T_{cr} \) is much lower than the pseudogap temperature, as found from the deviation of the linear resistivity. Sandu et al.\(^4\) have identified this critical temperature \( T_{cr} \) in the \( \rho_{ab}(T) \) data of their \( Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta} \) single crystals as a signature of the onset of dissipation due to thermally excited vortex loops. We will shortly compare \( T_{cr} \) with the onset temperature \( T_v \) of the anomalous Nernst voltage, which is a direct indicator of vortex loop excitations. At this juncture, it is also worthwhile to point out that the overall behavior of the \( \rho(T) \) of these films is similar to that observed by Convington and Green\(^5\) in their \( Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta} \) films. The important consequence of Pr doping is a significant enhancement in resistivity without affecting the linear temperature dependence of \( \rho \) at \( T \geq 120 \) K. This points towards enhanced scattering within CuO planes without affecting the carrier concentration as seen in Zn doped YBCO. At larger Pr concentrations \( x \geq 0.5 \), the \( \rho(T) \) curves develop an S shape similar to that seen in oxygen deficient YBCO in the vicinity of superconducting transition. This is a signature of reduction in carrier concentration.

The temperature dependence of Hall resistivity for all the films was measured in a 14 tesla field for both field orientations. Consistent with prior work (see Ref. 7 and 8), the normal state Hall coefficient \( R_H \) first increases as the temperature is lowered from 300 K and then drops near the superconducting transition. At a given temperature, the Hall number decreases with Pr doping. It is about 5 times smaller at \( T=300 \) K in the \( x=0.4 \) film than for the Pr-free sample suggesting a strong localization of mobile holes by the local field of the Pr ions. The temperature dependence of the Hall angle \( \cot \theta(T) \) for all the films was calculated. We find that the \( \cot \theta(T) \) data can be fitted to the form \( \cot \theta = a + bT^n \) with \( n \) close to 2. A similar temperature dependence of \( \cot \theta(T) \) in Pr-YBCO samples has been observed in previous reports.\(^3\)\(^,\)\(^10\)\(^,\)\(^11\)\ A deviation from the power law dependence of \( \cot \theta(T) \) on temperature is seen near \( T_c \) in all films. It has been suggested that this deviation could be related to the opening of the pseudogap.\(^12\) To find the temperature \( T_H \) where this deviation starts, we plot \( (\cot \theta - a)/bT^n \) as a function of temperature for the films (Fig. 2) with \( x \geq 0.2 \) and 0.3. As seen in the figure, \( (\cot \theta - a)/bT^n \) is a constant of order unity when the temperature is much higher than \( T_c \). It starts to increase sharply below a critical temperature \( T_H \sim 105 \) K for these two Pr content films. We actually find that \( T_H \) remains nearly independent of the Pr concentration. Since \( T_H \) which is close to \( T_{cr} \) found from the resistivity, is much lower than the pseudogap temperature, it has also been argued\(^12\) that the \( T_H \) scale may
be related to the onset of superconducting fluctuations or vortex-like excitations in the normal state.

The Nernst effect was measured in all Pr-substituted films. Fig. 3 shows the field dependence of the Nernst signal ($e_y$) at different temperatures for $x=0.2$ film. A qualitatively similar field dependence of $e_y$ was observed for the other concentrations of Pr. These data are not shown in Fig. 3 for the sake of clarity. The rapid rise of the Nernst signal for field less than the upper critical field ($H_{c2}$) observed for $T<T_c$ is due to the motion of vortices driven by the temperature gradient. At higher temperatures ($T>T_c$), the Nernst signal remains sizable and has a non-linear field dependence. On increasing the temperature well beyond $T_c$, the signal $e_y$ becomes extremely small. Here it tends to a negative linear field dependence, which typically is attributed to quasiparticles in the normal state.

The temperature dependence of the Nernst signal taken at 14 T for all the films is shown in Fig. 3. As seen in the figure, this signal is extremely small for all the films in the high temperature range well above $T_c$. On decreasing the temperature, the Nernst signal starts to increase rapidly at a certain temperature $T_{\nu}$, which depends on the Pr concentration. The temperature ($T_{\nu}$) below which the Nernst signal rises rapidly above the high temperature normal state data is marked by arrows in Fig. 3.

The large Nernst signal observed in the temperature window of $T_c$ and $T_{\nu}$ has been interpreted as evidence for vortex-like excitations or strong superconducting fluctuation in most of the hole-doped cuprates. In Fig. 3 we show the characteristic temperatures $T_{\nu}$, $T_H$, and $T_{cr}$ deduced from the measurements of resistivity, Hall angle and Nernst effect respectively along with the zero-field transition temperature $T_c$ as a function of Pr concentration. We note that the onset temperature of the anomalous Nernst signal $T_{\nu}$ is lower than $T_H$ and $T_{cr}$, and the difference between them increases in Pr-rich samples. It has been found that in hole-doped cuprates, the onset temperature of the anomalous Nernst signal compares well with the temperature at which a fluctuating diamagnetism appears, it is clear that $T_{\nu}$ is a true indicator of the emergence of vortex-like excitations in a phase in-
coherent condensate. We note that while the $T_c$ drops with increasing Pr, the width of the fluctuation regime $\Delta T_{fl} = T_{\nu} - T_c$ actually broadens.

The observed increase in $\Delta T_{fl}$ can be associated primarily with the out-of-plane disorder caused by the substitution of Pr at the Y sites of YBa$_2$Cu$_3$O$_7$. This site disorder may also have a spin component as the moment on the Pr sites can lead to pair breaking effects. Rullier-Albenque et al.\textsuperscript{6} have studied the effects of in-plane disorder on the Nernst effect in YBa$_2$Cu$_3$O$_7$ and YBa$_2$Cu$_3$O$_{6.6}$. They note that the fluctuation regime above $T_c$ expands considerably with the disorder. In Fig. 6 we plot the $T_{\nu}$ vs $T_c$ for Zn-doped YBCO. It is known that zinc causes a strong in-plane disorder with a drastic suppression of $T_c$. The normalized temperature $T_{\nu}$ of the zinc doped YBCO also follows the general trend seen in Fig. 6. A simple extrapolation of the curve shown in Fig. 6 suggests that a disorder-free YBa$_2$Cu$_3$O$_7$ should have a $T_c$ of 110K. In Fig. 6 we have also plotted the $T_{\nu}$ data of our films along with the results of Rullier-Albenque and coworkers. Quite remarkably, these data fall on a single curve with a slope $dT_{\nu}/dT_c \sim 0.36$. The figure also shows the characteristic temperature $T_{\nu}$ for Zn-doped YBCO which is consistent with the measurements on other YBCO cuprates with in-plane and out-of-plane disorders. However, we do not completely rule out the contribution of reduced carrier concentration, particularly in the Pr-rich sample ($x \approx 0.5$).

In summary, we have performed measurements of the Nernst effect, resistivity and Hall effect on Pr-substituted YBa$_2$Cu$_3$O$_{7-\delta}$ films. We find that an anomalous large Nernst signal survives above the superconducting transition temperature in the Pr-rich samples. This large Nernst voltage is attributed to vortex-like excitations in a phase incoherent superfluid existing above $T_c$. The regime of temperature over which these fluctuations prevail broadens with the Pr concentration. We attribute this effect primarily to the out-of-plane disorder caused by praseodymium, which is consistent with the measurements on other YBCO cuprates with in-plane and out-of-plane disorders. However, we do not completely rule out the contribution of reduced carrier concentration, particularly in the Pr-rich sample ($x \approx 0.5$).
