(Dated: February 1, 2008)

We investigate the temperature evolution of the electronic structure of ferromagnetic  $\text{CaB}_6$  using ultra-high resolution photoemission spectroscopy; electronic structure of paramagnetic  $\text{LaB}_6$  is used as a reference. High resolution spectra of  $\text{CaB}_6$  reveal finite density of states at the Fermi level,  $\epsilon_F$  at all the temperatures and evidence of impurity induced localized features in the vicinity of  $\epsilon_F$ , which are absent in the spectra of  $\text{LaB}_6$ . Analysis of the high resolution spectra suggests that disorder in B-sublattice inducing partial localization in the mobile electrons and low electron density at  $\epsilon_F$  is important to achieve ferromagnetism in these systems.

PACS numbers: 75.50.Pp, 71.55.Ak, 75.10.Lp, 71.23.-k

Discovery of unusual ferromagnetism in hexaborides,  $\text{MB}_6$  ( $M = \text{Ca, Sr, Ba}$  etc.) [1, 2] and in La-doped  $\text{CaB}_6$  [3] with high Curie temperature ( $T_C \geq 600$  K) has attracted a great deal of interest due to many interesting fundamental issues associated to this novel phenomena and huge potential in technological applications as well. Strikingly, none of the constituent elements in these compounds possess partially filled  $d$  or  $f$  levels to manifest ferromagnetism. In addition, the ground state of all the ferromagnetic compositions is very close to the band insulating phase [1, 2, 3, 4]. One school believes that ferromagnetism in these systems arises due to the polarization of low density conduction electrons (electron density slightly higher than the limit of Wigner crystallization) [3, 5]. Another school describes hexaborides as hole doped excitonic insulators (excitonic model) [6]. The later description was prompted by the observation of a band overlap at  $X$  point of the Brillouin zone in *ab initio* calculations [4] and subsequent description of the de Haas van Alphen and Shubnikov de Haas results [7, 8, 9] within the same framework. However, more recent *ab initio* calculations [10], and  $x$ -ray absorption and emission measurements [11] exhibit insulating phase in  $\text{CaB}_6$ . Angle resolved photoemission spectroscopic (ARPES) studies indicate an energy gap  $> 1$  eV at  $X$  point, which is too high for the suitability of excitonic model [11, 12].

In parallel, investigations by Matsubayashi *et al.* suggest that the ferromagnetism in  $\text{Ca}_{1-x}\text{La}_x\text{B}_6$  appears due to Fe impurities coming from the crucibles used for sample preparation [13]. However, the dependence of ferromagnetism on La concentration is curious. Subsequently, several experimental and theoretical studies are carried out to understand the origin of ferromagnetism in these systems. For example,  $\text{CaB}_6$  grown using Ca rich mixture of elements does not exhibit ferromagnetism but becomes weakly paramagnetic along with an increase in low temperature resistivity by more than two orders [1]. This observation suggests that ferromagnetism of the nominally pure system is related to the presence of vacancies in the

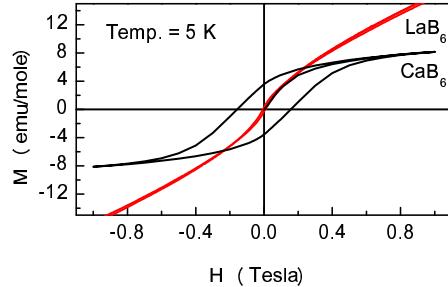

FIG. 1: (color online) Magnetic hysteresis curve of  $\text{CaB}_6$  and  $\text{LaB}_6$  taken at 5 K.

metal sublattice.  $\text{CaB}_6$  grown at different temperatures using high purity  $\text{CaO}$  and B show large differences in magnetic and resistivity behaviors [14]. A recent study [15] shows that tuning of Ca concentration and/or La doping does not lead to ferromagnetism if the samples are prepared using high purity (99.9999%) boron. Instead, the samples prepared using 99.9% pure boron exhibits ferromagnetism at certain compositions. A theoretical study [16] based on *ab initio* calculations suggests that ferromagnetism in  $\text{Ca}_{1-x}\text{La}_x\text{B}_6$  arises due to  $\text{B}_6$  vacancy and that the dominant contribution comes from the surface rather than the bulk. Another study attributed ferromagnetism of  $\text{CaB}_6$  to  $sp$  electrons in narrow impurity bands [17]. Ferromagnetic moment in  $\text{CaB}_6$  is observed to depend strongly on defect concentration [18].

It is clear that ferromagnetism in hexaborides is far from understood. In this letter, we report our results on the evolution of the electronic structure of  $\text{CaB}_6$  and  $\text{LaB}_6$  in the vicinity of the Fermi level,  $\epsilon_F$  as a function of temperature using state of the art high resolution photoemission spectroscopy.  $\text{LaB}_6$  is paramagnetic and hence, is used as a reference. High resolution spectra of  $\text{CaB}_6$  exhibit finite spectral intensity at  $\epsilon_F$ , despite the fact that it is predicted to be a band insulator. Temperature evolution reveals impurity features below  $\epsilon_F$  in

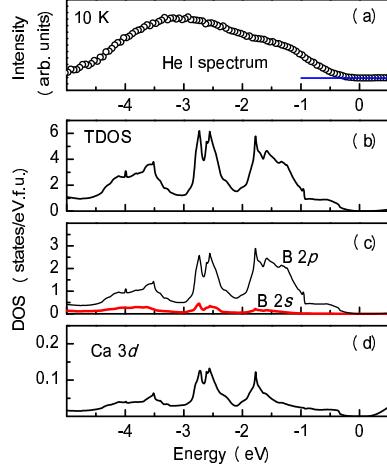

FIG. 2: (color online) (a) Valence band spectrum of  $\text{CaB}_6$  at 10 K. Calculated (b) TDOS, (c) B 2s and B 2p PDOS, and (d) Ca 3d PDOS.

$\text{CaB}_6$ , while  $\text{LaB}_6$  exhibits Fermi liquid behavior and a disorder induced dip at  $\epsilon_F$ .

$\text{CaB}_6$  and  $\text{LaB}_6$  were prepared in an arc furnace using 99.7% pure B powder, where all the ingredients were kept in a water cooled copper hearth and melted in ultra high pure argon atmosphere. Thus, the use of crucibles and hence the source of contaminations could be avoided. The high quality of the samples were ensured by sharp and intense x-ray diffraction (XRD) patterns. No trace of impurity was found in the XRD patterns. Magnetic measurements using high sensitivity vibrating sample magnetometer (VSM) and SQUID magnetometer exhibit clear hysteresis loop for  $\text{CaB}_6$  typical of a ferromagnetic material as shown in Fig. 1.  $\text{LaB}_6$ , however, does not exhibit hysteresis loop as evident in the figure. Photoemission measurements were performed using monochromatized UV source and electron analyzer, SES2002 from Gammadata Scienta at an energy resolution of 1.4 meV. The temperature variation down to 10 K was achieved by an open cycle He cryostat from Advanced Research Systems, USA. Band structure calculations were carried out using full potential linearized augmented plane wave (FLAPW) method within the local density approximations (LDA) using WIEN2K software [19]. The convergence was achieved considering 1000  $k$  points within the first Brillouin zone. The error bar for the energy convergence was set to  $< 0.25$  meV per formula unit and the charge convergence achieved was  $< 10^{-3}$  electronic charge.

In Fig. 2(a), we show the valence band spectrum of  $\text{CaB}_6$  collected at 10 K using He I radiations. There are two distinct features around 1.5 eV and 3 eV binding energies as also observed in previous ARPES study [12]. Intensity at  $\epsilon_F$  appears to be zero suggesting an insulating character of this material with a large gap. We show

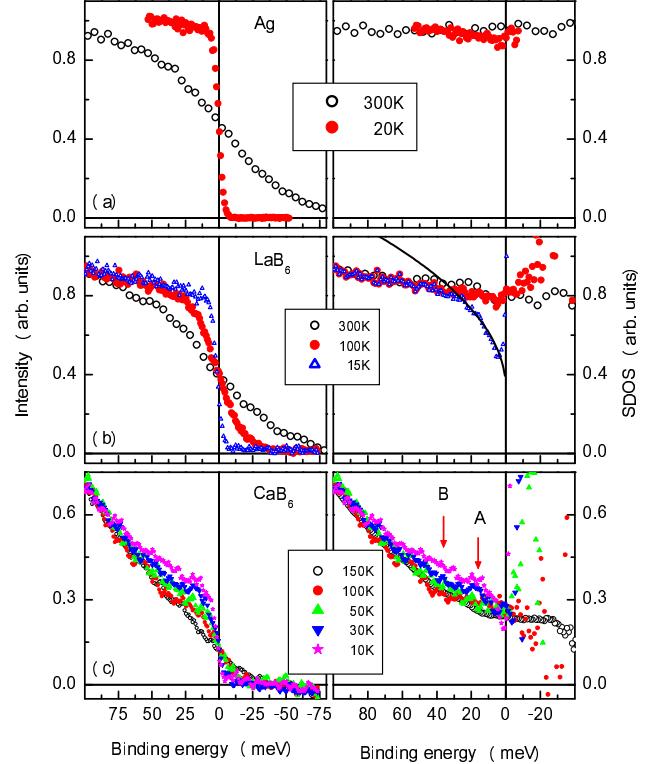

FIG. 3: (color online) He I spectra of (a) Ag, (b)  $\text{LaB}_6$  and (c)  $\text{CaB}_6$  in the vicinity of  $\epsilon_F$ . The right panels exhibit SDOS obtained by dividing the spectra in the left panel by the Fermi-Dirac distribution function.

the calculated total density of states (TDOS) in Fig. 2(b) and various partial density of states (PDOS) in Fig. 2(c) and 2(d). Interestingly, the LDA results exhibit an insulating ground state with an energy gap of about 0.2 eV characterizing  $\text{CaB}_6$  as a *band insulator*; the reproduction of the exact band gap may need other considerations [10, 20]. It is evident that the TDOS is primarily contributed by B 2p PDOS shown in Fig. 2(c). All other contributions (B 2s, Ca 3d, etc.) are significantly small in this energy range. Similar energy distribution of Ca 3d PDOS and B 2p PDOS, and the features above  $\epsilon_F$  (not shown here) indicate significant Ca 3d-B 2p covalency. The relative intensity of the features in the calculated results are slightly different from the experimental results presumably due to the fact that the experimental spectra are influenced significantly by the matrix element effects, lifetime broadening of the holes and electrons in addition to various other final states effects, which are not considered in the *ab initio* calculations. Interestingly, the energy positions of the features resemble remarkably well with the experimental features. All these results as well as the observation of similar band dispersions in previous studies [12] indicate that the influence from correlation effects is weak as expected for B 2p electrons.

While the spectrum in Fig. 2(a) exhibits no intensity

at  $\epsilon_F$ , very high resolution spectra, however, reveal a different scenario.  $\epsilon_F$  at various temperatures was determined experimentally by the Fermi cut off measured in Ag mounted on the same sample holder. This is demonstrated in Fig 3(a), where the valence band spectra of Ag at 300 K and 20 K crosses at  $\epsilon_F$ . Interestingly, all the spectra of CaB<sub>6</sub> shown in Fig. 3(c) exhibit finite intensity at  $\epsilon_F$ , which is consistent with the observation of Fermi surface in de Haas van Alphen measurements [9]. 150 K spectrum of CaB<sub>6</sub> exhibits negative slope near  $\epsilon_F$  indicating that  $\epsilon_F$  is pinned above the valence band. The intensity at  $\epsilon_F$  is very small and presumably arising due to the impurities and/or defects leading to charge carrier doping in this band insulating material.

All the spectra cross each other at  $\epsilon_F$  as expected from the temperature dependent Fermi-Dirac distribution function. However, the intensity below  $\epsilon_F$  increases unusually with the decrease in temperature. Such highly anomalous spectral evolution is not observed in LaB<sub>6</sub> as shown in the middle panel of the figure. We have divided all the spectra in the left panel of Fig. 3 by the Fermi-Dirac distribution function. The high energy resolution employed in these measurements introduce negligible resolution broadening in the experimental spectra. Thus, such divided spectral functions are a good representation of the spectral density of states (SDOS) as often observed in other systems [21, 22]. SDOS at different temperatures for all the three samples, Ag, LaB<sub>6</sub> and CaB<sub>6</sub> are shown in the right panel of the figure. SDOS of Ag exhibits a flat distribution of intensity as a function of binding energy as expected for bulk Ag. LaB<sub>6</sub> also exhibits essentially flat and temperature independent SDOS down to 100 K. Further decrease in temperature leads to a sharp dip at  $\epsilon_F$  with a lineshape,  $I(\epsilon) = I_o + a \times |\epsilon - \epsilon_F|^\alpha$ , where  $\alpha = 0.5$  (solid line in the figure). This suggests that disorder plays an important role in determining the electronic structure in this system [23] in addition to the electron-phonon coupling effect predicted before [24, 25].

Strikingly different behavior is observed in CaB<sub>6</sub>. The intensity at  $\epsilon_F$  remains almost unchanged down to the lowest temperature studied. Most interestingly, the intensity below  $\epsilon_F$  increases gradually with the decrease in temperature. The growing features are manifested by a double peak structure marked by 'A' and 'B' in the figure. In order to probe the features more clearly, we have derived the spectral functions at lower temperatures by convoluting the SDOS at 150 K with Fermi-Dirac distribution function. The simulated spectra represented by solid lines are compared with the experimental spectra (symbols) in Fig. 4(a). Clearly, the experimental spectra exhibit much enhanced intensity compared to that expected merely due to the thermal effects included in the Fermi-Dirac distribution function. We have subtracted the 150 K spectrum from all the spectra at low temperatures to find the spectral weight transfer, which are shown in Fig. 4(b). The smooth lines through the

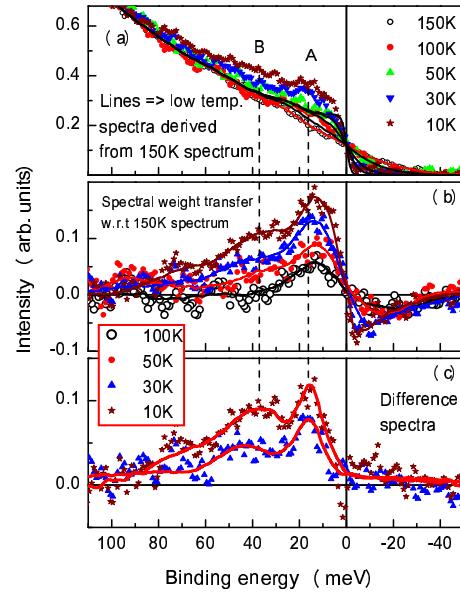

FIG. 4: (color online) (a) He I spectra of CaB<sub>6</sub> at different temperatures. The lines represent the low temperature spectra derived from SDOS at 150K. (b) The temperature induced spectral weight transfer calculated by subtracting 150 K spectrum from all the other spectra. (c) Difference spectra at 30 K and 10 K obtained by subtracting the lines in (a) from the corresponding raw data.

points are drawn to guide the eye. The zero intensity at  $\epsilon_F$  indicates that the DOS at  $\epsilon_F$  remain essentially unchanged. Two distinctly separable features are observed at about 15 meV and 36 meV binding energies. In Fig. 4(c), we show the difference spectra at 30 K and 10 K after subtracting corresponding estimated spectral functions shown in Fig. 4(a). Interestingly, the temperature induced changes at the Fermi edge are not visible in Fig. 4(c). This reveals the fact that the delocalized density of states follow the Fermi-Dirac distribution function and may be described within Fermi liquid picture. The features A and B are weakly localized and manifested at low temperatures due to less degree of thermal excitations.

These results thus clearly suggest that small impurities ( $\sim 0.3\%$ ) in B-sublattice introduce localized electronic states just above the valence band. The double peak structure and their intensity ratio suggest 2p character of the electrons with a spin-orbit splitting of about 20 meV. This is not unlikely, since the valence band is constituted essentially by B 2p electronic states. These features are not observed in LaB<sub>6</sub>, despite the fact that both the samples are prepared using identical procedure. Instead, the spectra in LaB<sub>6</sub> exhibit a dip at  $\epsilon_F$ . LaB<sub>6</sub> is a good metal with large conduction electron density ( $\approx 10^{22} \text{ cm}^{-3}$ ) at  $\epsilon_F$ , which presumably smears out the local features suggesting that the conduction electron density plays an im-

portant role here.

The crystal structure of the hexaborides consists of two interpenetrating cubic lattice formed by metals and  $B_6$  octahedra. The B-sublattice is very stable, robust and essentially B 2p electrons determines the electronic properties. The impurities in B introduce significant disorder as clearly observed in  $LaB_6$  in addition to doping of charge carriers. This has twofold effects. While disorder leads to local moments via localization effect, the delocalized character of the doped carriers helps to mediate exchange interactions resulting to long range order. This scenario explains the studies performed so far on various samples. For example, it is observed [15] that samples prepared with 99.9999% purity B do not exhibit ferromagnetism despite the tuning of charge carrier density by changing the Ca-concentration. It is thus clear that merely change in carrier concentration and/or vacancies in Ca or B sublattice do not lead to ferromagnetism. On the other hand, samples such as  $CaB_6$ ,  $Ca_{1-\delta}B_6$ ,  $Ca_{1-x}La_xB_6$  prepared with poorer B purity exhibit ferromagnetism when the carrier concentration is low. In every case, the impurities in B-sublattice, vacancies and/or La substitutions dope low density charge carriers of 2p character. These charge carriers are partially localized (binding energy  $\sim 15$  mev) due to disorder and are responsible for ferromagnetism. It is to note here that ferromagnetism due to 2p electrons has been predicted in other systems such as C impurities in BN nanotubes [26].

In summary, high resolution spectra of ferromagnetic  $CaB_6$  exhibit finite density of states at  $\epsilon_F$  and emergence of distinct weakly localized features below  $\epsilon_F$ , which is not observed in paramagnetic  $LaB_6$ . The details of the temperature evolutions of the high resolution spectra suggests that there are two parameters that are important to derive ferromagnetism in hexaborides; disorder in the B sublattice and conduction electron density.
