**Key words:** Nonlinear ray theory, shock ray theory, shock propagation, curved shock, conservation laws, shock dynamics, blast waves, piston problems.

## Abstract

Shock ray theory (SRT) has been found to be quite useful and computationally efficient in finding successive positions of a curved weak shock front. In this article we solve some piston problems and show that the shock ray theory with two compatibility conditions gives shock positions, which are very close to those obtained by solving the same problems by numerical solution of Euler's equations (Euler Solutions). Comparison of the results obtained by shock ray theory and geometrical shock dynamics (GSD) of Whitham with Euler solution shows that the shock ray theory gives more accurate results for any piston motion. Aim of the work is not just this comparison but also in investigating the role of the nonlinearity in accelerating the process of evolution of a shock, produced by an explosion of a non-circular finite charge, into a circular shock front. We find that the nonlinear waves propagating on the shock front appreciably accelerate this process. We also discuss a situation, for shock Mach number very close to 1, when GSD and shock ray theory may fail to give any result.

## 1 Introduction

A blast wave produced by an explosion of a charge of finite size will initially have a non-spherical shape, or rather non-circular shape for this paper since we consider here only

---

Email: prasad@math.iisc.ernet.in

the propagation of a cylindrical shock described in  $(x, y)$ -plane. The initial shape will be non-circular not only because the explosive may be packed in a non-circular container but also because all parts of the explosion would not burn simultaneously. After a long time, when the leading shock has traveled a large distance compared to the linear dimensions of the explosion, the shock front will be almost circular even according to the linear theory. However, nonlinearity present in the Euler's equations of motion (we consider propagation of the shock front in a polytropic gas) will tend to smoothen the geometry of the shock front due to nonlinear waves propagating on the shock front itself and the shock front may become almost circular much earlier. We shall like to investigate this phenomenon by the shock ray theory. Prasad (1993) first derived the shock ray theory for a weak shock directly from the transport equations along a shock ray for a shock of arbitrary strength and later Monica and Prasad (2001) derived it from a weakly nonlinear ray theory (which we shall briefly refer as nonlinear ray theory through out this paper) (see Prasad 2001 for all references and a detailed discussion). The nonlinear ray theory (Prasad, 2000) is a WKB theory, generalized to a hyperbolic system of quasi-linear equations. The shock ray theory is ideally suited for this investigation since

- (i) it provides the shock as a well defined sharp curve in computational results,
- (ii) it requires very small computational time to give successive positions of the shock - in fact only a fraction of the time required for computing shock position by numerical solution of Euler's equations called Euler solution in this paper,
- (iii) it gives a critical time  $t_c$ , an estimate of the time when the shock curve is very nearly a circle and
- (iv) it gives results very close to those obtained by solving Euler's equations.

Shock ray theory consists of shock ray equations (Prasad 1982) and an infinite system of compatibility conditions along these rays (Grinfel'd 1978; Maslov 1980). However, the system of equations for successive compatibility conditions becomes too complex to be of any use. Suitable truncation of these equations in  $n$ th compatibility condition leads to a finite system of equations (Ravindran and Prasad 1990), which simplify considerably for a weak shock (Prasad 1993; Monica and Prasad 2001). When we refer to the shock ray theory in this paper, we mean the ray equations with two compatibility conditions and with suitable truncation in the second compatibility condition for a weak shock. Kevlahan (1996) provided an evidence for the property (iv) for shock ray theory by comparing its results with some known exact solutions, with experimental results and some numerical solutions of Euler's equations. Since, Kevlahan did not have the conservation form of the equations of shock ray theory, his comparison with Euler's results is only for a limited time. In this paper we show that there is an excellent agreement of the results of shock ray theory with Euler solution through an extensive numerical computation even for those cases in which there is some doubt for the validity of shock ray theory i.e. when the curved piston is accelerating.

In section 2 we give a new formulation of the conservation forms of the two compatibility conditions used in shock ray theory here. These conservation forms appear to be more natural and follow a pattern, which are valid for each of the infinite set of compatibility

conditions for a curved shock of an arbitrary strength. In section 3 we derive the initial condition to set up the initial value problem for the system of equations of the shock ray theory appropriate to the flow produced by the motion of a curved piston. In the subsequent sections we present the results of three problems solved by shock ray theory and compare the results of shock ray theory, Euler solution and results of geometrical shock dynamics (GSD) by Whitham (1957).

The presence of the nonlinear ray theory results provides an excellent opportunity for the purpose of comparison of the results. In the theory of a *weak shock* all important features of the shock arise over a distance which is the distance between the linear wavefront and the shock. This is the reason that we study weak shock governed by  $u_t + (a_0 + \epsilon u)u_x = 0$ , where  $\epsilon$  is a small quantity, by the model equation  $u_{t'} + uu_{x'} = 0$  with  $t' = t$ ,  $x' = (x - a_0 t)/\epsilon$ . From a general theorem (Theorem 9.2.1, page 267, Prasad 2001), it follows that this distance, which is the displacement (measured suitably for a multi-dimensional shock) of a weak shock from the linear wavefront, is of the same order as the displacement of the nonlinear wavefront (by nonlinear ray theory) from the weak shock. The nonlinear wavefront has the same topological shape as the shock. Therefore, an error in the position of the GSD (and shock ray theory) is to be calculated in terms of the ratio of the distance (appropriately defined) of the GSD shock (or shock ray theory shock) from the Euler solution shock, to the distance of the GSD shock (or shock ray theory shock) from the nonlinear wavefront. Another quantity, which is important for comparison is the measurement of the shock strength, which has been done by Monica and Prasad (2001). The GSD shock, while propagating in an uniform medium, does not decay (amplify) but shock ray theory shock does as, it should be, when waves from behind catch it up and modify the shock strength for an decelerating (accelerating) piston problem.

Since no estimation of the error of the shock ray theory seems to be possible, specially for curved shocks, and theory is very important from the point of view of applications, for example, from focused sonic boom in aviation (Plotkin 2002) to shock wave lithotripsy to treat kidney stone disease (Sturtevant 1989), it is important to compare the results of shock ray theory with Euler's results. This has become more important because the GSD have been used to predict finer results of the shape of shock fronts in some limiting cases (Swendenmann 2002; Apazidis, et al. 2002). Even if a theory has only 5% error, the limiting results may be completely wrong. Hence the comparison of the results by shock ray theory, GSD and Euler's equations, which we have presented are valuable. This comparison becomes more important for us because we wish to answer the question raised in the beginning of this introduction "how does the nonlinearity present in Euler's equations accelerate the process of a non-circular shock to become circular?". The answer to this question is provided by shock ray theory in the end of the section 6 and therefore we must examine the reliability of the results of shock ray theory. We find an excellent agreement between the results of shock ray theory and Euler's results, where as those between GSD and Euler's results are not so good. We also discuss some limitations in application of nonlinear ray theory, GSD and shock ray theory in solving a piston problem with a convex corner in the piston.

## 2 Conservation form of the equations of shock ray theory

Let us consider a cylindrical shock propagating into a polytropic gas at rest and in uniform state  $(\rho, \mathbf{q}, p) = (\rho_0, \mathbf{0}, p_0)$ , where  $\rho$  is the density,  $\mathbf{q} = (q_1, q_2)$  the velocity and  $p$  is the pressure. Let  $a$  be the sound velocity in the medium:  $a^2 = \gamma p / \rho$ , where  $\gamma$  is the ratio of specific heats. Propagation of such a shock can be studied in  $(x, y)$ -plane. We assume the shock to be produced by the motion of a curved piston. Before proceeding further, we introduce a non-dimensional coordinate system with the help of a length  $L$  and the sound velocity  $a_0$  in the uniform state. We choose  $L$  to be a length of the order of the linear dimension of the piston. We denote the non-dimensional coordinates also by the same symbol  $(x, y, t)$ . The basic equations from which the shock ray theory has been derived are the well known Euler equations.

We assume the piston to be at rest for  $t < 0$  and then start moving suddenly with a small non-zero velocity at  $t = 0$  and with a small acceleration. This produces a shock front initially coincident with the piston. The shock will be followed by a one-parameter family of nonlinear wavefronts which are also the result of the piston motion. But these nonlinear wavefronts are identifiable only over a small distance behind the shock, because the high-frequency (or the short-wave approximation) is valid only over such a distance from the shock. It also follows that *the unit normal to the shock front and that of any one of the nonlinear wavefronts behind it are approximately the same.*

Let  $\mathbf{N} = (\cos \Theta, \sin \Theta)$  be the unit normal of the shock front. Assuming the shock to be weak, the perturbation in density  $\rho$ , fluid velocity  $\mathbf{q}$  and pressure  $p$  up to a short distance behind the shock are given by (see Prasad 2001, Chapter 10)

$$\rho - \rho_0 = \rho_0 w, \quad \mathbf{q} = \mathbf{N} a_0 w, \quad p - p_0 = \rho_0 a_0^2 w, \quad (2.1)$$

where  $w$  is of the order of a small quantity  $\epsilon$ , which is a measure of the shock strength. We denote the value of  $w/\epsilon$  on the shock front by  $\mu$  and the Mach number of the shock by  $M$ , and they are given by

$$\mu = (w/\epsilon)|_{\text{shock front}}, \quad M = 1 + \epsilon \frac{\gamma + 1}{4} \mu. \quad (2.2)$$

Under a short wave assumption  $\langle \mathbf{N}, \nabla \rangle w$  is assumed to be of order 1. We now define a quantity  $V$  by

$$V = \frac{\gamma + 1}{4} \{ \langle \mathbf{N}, \nabla \rangle w \} |_{\text{shock front}}. \quad (2.3)$$

Note that this quantity was earlier denoted by  $N$  (Prasad 2001; Monica and Prasad 2001) and is of  $O(1)$ .

We introduce a ray coordinate system  $(\xi, t)$  such that  $\xi = \text{constant}$  are shock rays in the  $(x, y)$ -plane and  $t = \text{constant}$  are successive positions of the shock. Let  $G$  be the metric associated with  $\xi$  (see Prasad, 2001, for the definition), and  $(X, Y)$  be a point on

the shock at time  $t$ . The equations of shock ray theory for a weak shock are (Monica and Prasad 2001, Prasad 2001, these references may be consulted for detailed explanation of all concepts mentioned briefly here)

$$X_t = M \cos \Theta, \quad Y_t = M \sin \Theta, \quad (2.4)$$

$$\Theta_t + \frac{1}{G}M_\xi = 0, \quad G_t - M\Theta_\xi = 0, \quad (2.5)$$

$$M_t + \frac{M-1}{2G}\Theta_\xi + (M-1)V = 0, \quad V_t + \frac{V}{2G}\Theta_\xi + 2V^2 = 0. \quad (2.6)$$

If we eliminate  $\Theta_\xi$  between the second of (2.5) and the first of (2.6), we get the equation

$$\frac{2M}{M-1}M_t + \frac{G_t}{G} + 2VM = 0. \quad (2.7)$$

In order to discuss shocks in the solutions of system (2.5)-(2.6), in  $(\xi, t)$ -plane, we need the system to be in conservation form. Two physically realistic conservation laws, called kinematical conservation laws (KCL), representing conservation of distance in two independent directions and equivalent to (2.5) for differentiable functions  $M, \Theta$  and  $G$ , are

$$(G \sin \Theta)_t + (M \cos \Theta)_\xi = 0, \quad (G \cos \Theta)_t - (M \sin \Theta)_\xi = 0. \quad (2.8)$$

We derive now two more new conservation forms, which not only follow a general pattern valid for all compatibility conditions, but are particular cases for a shock of arbitrary strength (Prasad 2004). We notice in the equations (2.6) for the shock strength  $M-1$  and the gradient  $V$  behind the shock that the second terms have a coefficient  $\Theta_\xi/(2G)$ , which represents geometric amplification of decay of the corresponding quantities  $M-1$  and  $V$  respectively. To derive a conservation form of the equations involving  $M-1$ , we take the equation (2.7), which gives a combination  $\{F'(h)/F(h)\}h_t + G_t/G$  where  $h = M-1$  and  $F$  is a known function of  $h$ , or more specifically  $F(h) = h^2 e^{2h}$ , leading to the conservation form

$$\{G(M-1)^2 e^{2(M-1)}\}_t + 2M(M-1)^2 e^{2(M-1)}GV = 0. \quad (2.9)$$

Similarly, eliminating  $\Theta_\xi$  between the second of (2.5) and the second of (2.6), we get an equation which we rewrite as

$$V_t + \frac{V}{2G}G_t + \frac{V}{2} \left( \frac{1}{M} - 1 \right) \frac{G_t}{G} + 2V^2 = 0.$$

We use (2.7) to replace  $G_t/G$  in the third term by  $-2MM_t/(M-1) - 2VM$  (note  $M_t = (M-1)_t$ ), which gives the conservation form

$$\{GV^2 e^{2(M-1)}\}_t + GV^3(M+1)e^{2(M-1)} = 0. \quad (2.10)$$

The conservation forms (2.9) and (2.10) of the compatibility conditions (2.6) respectively appear to be physically realistic and are different from those used by Monica

and Prasad, (2001). In the linear theory, the energy conservation along with a ray tube is represented by  $\{G(M - 1)^2\}_t = 0$ , which can be written in an integral formulation using two cross sections of a ray tube (see equation (7.69) and the next equation, Whitham, 1974). Nonlinearity seems to bring in a factor  $e^{2(M-1)}$  as seen in the Chapter 4 on nonlinear ray theory of Prasad (2001) (see also Prasad and Sangeeta 1999) and the dissipation of energy through a shock is represented by the source terms in equations (2.9) and (2.10). Any other form containing an expression  $\{f(GF(h))\}_t$ , where  $f : \mathbb{R} \rightarrow \mathbb{R}$  is a monotonic function also appears to give appropriate geometrical decay or amplification of  $h$ . In this case, a jump relation across a shock is given by  $G_r F(h_r) = G_l F(h_l) \Leftrightarrow f(G_r F(h_r)) = f(G_l F(h_l))$ , where  $l$  and  $r$  represents the states on the two sides of a shock.

The system of four equations (2.5)-(2.6) is hyperbolic for  $M > 1$ , which is true for a shock. Thus, we get a system of four equations in conservation form: (2.8)-(2.10), which is hyperbolic for a shock front. Given a solution of this system, we solve (2.4) as ordinary differential equations for each value of  $\xi : (X = X(\xi, t), Y = Y(\xi, t))$ , which give the position of the shock front at a fixed time  $t$  and a ray for a fixed  $\xi$ . Given an initial position of a shock  $\Omega_0 : (X_0(\xi), Y_0(\xi))$  (so that we can compute  $\Theta_0(\xi)$ ), initial shock strength  $M_0(\xi)$  and initial gradient  $V_0(\xi)$  of the flow behind  $\Omega_0$ ; we can set up an initial value problem of shock ray theory equations (2.4) and (2.8)-(2.10)

$$X(\xi, 0) = X_0(\xi), Y(\xi, 0) = Y_0(\xi), \Theta(\xi, 0) = \Theta_0(\xi), M(\xi, 0) = M_0(\xi), V(\xi, 0) = V_0(\xi).$$

The problem of finding successive positions of a shock front is reduced from a 3-dimensional problem of solving the Euler's equations in  $(x, y, t)$ -space to that of solving the shock ray theory equations in  $(\xi, t)$ -plane. This reduction of one dimension leads to a considerable computational efficiency. In fact, in the case of problems we have solved in this paper, shock ray theory takes only less than 10% of time required for solving Euler's equations. Moreover, since we need to solve a system of hyperbolic equations in conservation form, we can use highly sophisticated and powerful numerical schemes. In this work, we used discontinuous Galerkin finite element method (Corkburn et al., 1989) for solving the hyperbolic system. Further, we have used source term splitting method for the inhomogeneous terms appearing in shock ray theory and Strang dimension splitting method for solving 2-dimensional Euler system. In the next section we determine the initial values for the shock ray theory equations for a shock front produced by an impulsive motion of a curved piston.

### 3 Initial conditions for shock ray theory equations for a piston problem

Consider now the disturbance produced by an impulsive motion of a piston. For a small time, the distance between the shock and the piston is small compared to the extent of the piston. Thus, in the initial stages, the entire flow produced by the piston satisfies the high frequency or the short wave approximation (this is in contrast to the situation for a large

time, when only the flow immediately behind the shock satisfies this approximation). For a small time, we can now visualize the flow between the piston and the shock to be generated by a one parameter family of nonlinear wavefronts. For such a small time, we take the unit normal  $\mathbf{n}_p$  of the piston to be equal to those of the nonlinear wavefronts  $\mathbf{n}$  and the shock  $\mathbf{N}$  (i.e.  $\mathbf{n}_p = \mathbf{n} = \mathbf{N}$ ). A moving curve is associated with a ray coordinate system  $(\xi, t)$  of its own. In principle, we can choose the ray coordinate system of the piston to be different from that of any one of the nonlinear wavefronts and that of the shock. We can do this in spite of a condition we impose that in the limit as  $t$  tends to zero, the variable  $\xi$  appearing in these is same as  $\xi$  of the piston, which we can choose (at  $t = 0$ ) to be the arc length along the piston. However, in order to derive the initial conditions for the shock ray theory equations, we shall equate the  $\xi$ -derivatives along all these curves and hence we need to choose the ray coordinate system of the piston to be such that  $\xi$  is not only the arc length along the initial position of the piston but  $\xi = \text{constant}$  and  $t = \text{constant}$  curves form an orthogonal system in  $(x, y)$ -plane, as in the case of the shock front and a non-linear wavefront. This choice means that if the piston surface is represented by

$$(x, y) = (x_p(\xi, t), y_p(\xi, t)), \quad (3.1)$$

then

$$\mathbf{n}_p = \mathbf{x}_{pt} / |\mathbf{x}_{pt}|. \quad (3.2)$$

Let the equation of the shock be represented by  $(x, y) = (X(\xi, t), Y(\xi, t))$ , then

$$X_0(\xi) = X(\xi, 0) = x_p(\xi, 0), \quad Y_0(\xi) = y(\xi, 0) = y_p(\xi, 0) \quad (3.3)$$

Therefore, we can calculate  $\Theta_0(\xi)$  from the initial shape of the piston. Now, we proceed to calculate  $M_0(\xi)$  and  $V_0(\xi)$ . We note that the boundary condition at the piston in an inviscid flow is given by “*the fluid speed on the piston in the normal direction is equal to the piston speed in the normal direction*”. This gives

$$w(\mathbf{x}_p(\xi, t), t) \equiv \langle \mathbf{n}_p(\xi, t), \mathbf{q}(\mathbf{x}_p(\xi, t), t) \rangle = \langle \mathbf{n}_p(\xi, t), \mathbf{x}_{pt}(\xi, t) \rangle = |\mathbf{x}_{pt}|. \quad (3.4)$$

From (2.2) and (3.4), we get

$$M_0(\xi) = 1 + \frac{\gamma + 1}{4} |\mathbf{x}_{pt}|. \quad (3.5)$$

The transport equation for the amplitude  $w$  (from nonlinear ray theory, equation (10.1.4), Prasad 2001) takes the form

$$w_t + \left(1 + \frac{\gamma + 1}{2} w\right) \langle \mathbf{N}, \nabla \rangle w = \Omega w, \quad (3.6)$$

where  $\Omega = -\frac{1}{2} \langle \nabla, \mathbf{N} \rangle$  is the mean curvature of a nonlinear wavefront behind the shock front in the short wave limit. Taking its limit as we approach the piston, we get after using (3.4)

$$w_t|_p + \left\{1 + \frac{\gamma + 1}{2} |\mathbf{x}_{pt}|\right\} \langle \mathbf{n}_p(\xi, t), \nabla \rangle w|_p = (\Omega w)|_p. \quad (3.7)$$

We shall now encounter two types of partial derivatives with respect to  $t$ , one when  $\mathbf{x}$  is kept fixed and another when  $\xi$  is kept fixed. The result (3.4) is valid for all  $t > 0$  and taking its derivative with respect to  $t$ , we get

$$\{w_t|_p + (\langle \mathbf{x}_{pt}, \nabla \rangle w)|_p\} = \langle \mathbf{x}_{pt}, \mathbf{x}_{ptt} \rangle / |\mathbf{x}_{pt}| = \langle \mathbf{n}_p, \mathbf{x}_{ptt} \rangle.$$

which at  $t = 0$ , after using (3.2), becomes

$$w_t|_{p,t=0} + |\mathbf{x}_{pt}(\xi, 0)| \langle \mathbf{n}_{p0}, \nabla \rangle w|_{p,t=0} = \langle \mathbf{n}_p, \mathbf{x}_{ptt} \rangle|_{t=0} \quad (3.8)$$

Setting  $t = 0$  in (3.7) and eliminating  $w_t|_{p,t=0}$  between (3.7) and (3.8), we get (we note  $\Omega|_{t=0} =$  mean curvature of the piston at  $t = 0$  is equal to  $\Omega_p|_{t=0}$  and use  $\mathbf{n}_{p0}$  for  $\mathbf{n}_p(\xi, 0)$ )

$$\begin{aligned} & \left\{ \left( 1 + \frac{\gamma + 1}{2} w|_{p,t=0} \right) - |\mathbf{x}_{pt}(\xi, 0)| \right\} \{ \langle \mathbf{n}_{p0}, \nabla \rangle w|_{p,t=0} \} \\ & = (\Omega_p|_{t=0} w|_{p,t=0}) - \langle \mathbf{n}_{p0}, \mathbf{x}_{ptt}(\xi, 0) \rangle. \end{aligned} \quad (3.9)$$

We now use (3.4) in (3.9) and note (2.3) to derive the initial value  $V(\xi, 0) = V_0(\xi)$  as

$$V_0(\xi) = \frac{\gamma + 1}{4 \left\{ 1 + \frac{\gamma - 1}{2} \langle \mathbf{n}_{p0}, \mathbf{x}_{pt}(\xi, 0) \rangle \right\}} [\Omega_p|_{t=0} |\mathbf{x}_{pt}(\xi, 0)| - \langle \mathbf{n}_{p0}, \mathbf{x}_{ptt}(\xi, 0) \rangle]. \quad (3.10)$$

Note that the values  $M_0(\xi)$  and  $V_0(\xi)$  are completely determined by (3.5) and (3.10) in terms of the initial shape and initial motion of the curved piston. The initial value  $G_0 = G(\xi, 0)$  is obtained from the initial geometry of the shock front, which is the same as that of the piston. Hence

$$G_0(\xi) = |\mathbf{x}_{p\xi}(\xi, 0)| \quad (3.11)$$

In this paper, we shall use very simple geometrical forms of the piston, which will be either a symmetrically expanding square or a curve made of a number of straight segments and moving as a rigid line in the direction of a symmetry. Then  $\mathbf{n}_{p0}$  is piecewise constant i.e.,  $\Omega_p = 0$  except for a set  $S$  of isolated points and also  $\mathbf{n}_{pt} = 0$  except for  $S$ . In this case, the expression for  $V_0(\xi)$  simplifies considerably to

$$V_0(\xi) = - \frac{\gamma + 1}{4 \{ 1 + \frac{\gamma - 1}{2} |\mathbf{x}_{pt}| \}} \langle \mathbf{n}_{p0}(\xi), \mathbf{x}_{ptt}(\xi, 0) \rangle. \quad (3.12)$$

Note that in  $\mathbf{x}_{pt}$ , the time derivative of  $\mathbf{x}_p$  is with  $\xi = \text{constant}$  i.e.,  $|\mathbf{x}_{pt}|$  is the normal speed of the piston.

## 4 Other theories

In this section, we shall describe other theories, with which we shall compare the results of shock ray theory. The simplest of these is the linear theory. This is a well known theory, in which rays in a uniform medium are straight lines and the wavefront is given by Huygen's method. It is also well known that in the linear theory, the ray method from a *smooth* part of the initial wavefront gives same wavefront as the *Huygens' method* but the ray method fails near singularities of the initial wavefront.

## 4.1 Weakly nonlinear ray theory (Nonlinear ray theory)

When we consider a shock front behind which the flow satisfies high frequency or short wave length approximation, the shock front is followed by a one parameter family of nonlinear waves. These waves, when weak, follow the weak shock front, catch up with the shock, interact and then disappear from the flow. The evolution of any one of these wavefronts is also governed by the kinematical conservation laws (see Prasad 2001)

$$(g(m) \sin \theta)_t + (m \cos \theta)_\xi = 0, \quad (g(m) \cos \theta)_t - (m \sin \theta)_\xi = 0, \quad (4.1)$$

where  $m$  is the Mach number of the weakly nonlinear wavefront,  $\theta$  the angle between the normal to the wavefront and the  $x$ -axis, and the metric  $g$  associated with the coordinate  $\xi$  is given by

$$m = 1 + \frac{\gamma + 1}{2} w, \quad g(m) = (m - 1)^{-2} e^{-2(m-1)} \quad (4.2)$$

provided the variable  $\xi$  is chosen suitably.

The system (4.1) is hyperbolic if  $m > 1$  and (2.1) implies that the pressure  $p$  on the wavefront is greater than that in the ambient medium. We only consider the case when  $m > 1$ . Once we get a solution  $m = m(\xi, t)$ ,  $\theta = \theta(\xi, t)$  of (4.1), we can get the position of the wavefront by solving

$$x_t = m \cos \theta, \quad y_t = m \sin \theta \quad (4.3)$$

The system of equations (4.1) and the ray equations (4.3) forms the nonlinear ray theory and gives the complete history of weakly nonlinear waves which are continuously produced by the piston. A weakly nonlinear wave, which instantaneously coincides with the shock front, heading the disturbance in the piston problem, is produced by the piston not at the time  $t = 0$  when the shock is produced but at a later time. But we compare the history of a nonlinear wavefront with that of the shock because the evolution of both are topologically and qualitatively same, and the geometrical shock dynamics (GSD) is almost the same as the nonlinear ray theory except that the relation for  $m$  in (4.2) is replaced by (2.2). In this paper, we shall discuss only one nonlinear wavefront, the one that was produced by the piston at the same time as the shock was produced; but this is done only as an academic exercise because it is annihilated by the shock as soon as it is produced. We only calculate its geometry and position without bothering that it really does not exist. The initial condition for  $\theta$  for this weakly nonlinear wavefront are the same as those for  $\Theta$  in the section 3 (i.e.,  $\theta(\xi, 0) = \theta_p$ ) and that for  $m$  is  $m(\xi, 0) = 1 + (\gamma + 1/2)w|_p = m_0$ , say.

## 4.2 Whitham's geometrical shock dynamics

The kinematical conservation laws (2.8) (or (4.1)) governs the evolution of any moving curve in a plane. The additional closure equations such as (2.9) and (2.10) in shock ray theory or (4.2) for nonlinear ray theory come from the dynamics of the curve. Whitham

did not have the kinematical conservation laws but derived its differential form (2.5), and then using his valuable insight into the physics of the problem provided a closure relation (now well known as A - M relation), which for a weak shock becomes

$$G(M) = (M - 1)^{-2} \quad (4.4)$$

provided we again choose the variable  $\xi$  suitably. Note that for a weak shock, the ray tube area  $A \propto (M - 1)^{-2}$ . The two relations (4.2) and (4.4) agree up to the first term in the expansion of the right hand side of (4.2) for small  $m - 1$ . Whitham's intuition, which led to (4.4), clearly show the self-propagation property, a property characteristic of weakly nonlinear wavefronts (Prasad 1995; also see Prasad 2001) but was used for a shock front. By GSD, we shall mean here not the differential form of equations by Whitham but kinematical conservation laws (2.8) along with (2.4) and (4.4). One of our main aims in this paper is to compare the results of shock ray theory and GSD with Euler solution.

### 4.3 Euler's equations of motion

Conservation form of the Euler equations of motion of a polytropic gas are well known. We have already commented on non-dimensionalization of space and time coordinates in section 2. We include that and additional non-dimensional variables (with ')

$$\rho' = \rho/\rho_0, \mathbf{q}' = \mathbf{q}/a_0, p' = p/(\gamma p_0), \mathbf{x}' = \mathbf{x}/L, t' = a_0 t/L \quad (4.5)$$

and then drop ' from the non-dimensional variables in the transformed equations. The non-dimensional form of the Euler equations remain same as the original equations.

The equilibrium state ahead of the shock (or the nonlinear wavefront) is  $(\rho_0, \mathbf{q}_0, p_0) = (1, 0, 1/\gamma)$ , so that the perturbation (2.1) becomes

$$\rho = 1 + w, \quad \mathbf{q} = \mathbf{N}w, \quad p = \frac{1}{\gamma} + w. \quad (4.6)$$

The shock and nonlinear wavefront Mach numbers are given by (2.2) and (4.2) respectively. Given the piston motion and its geometry in the form (3.1), we can use (3.5) and (3.10) (or (3.12)) to set up initial value problem for shock ray theory; (3.5) alone for GSD and

$$m(\xi, 0) = 1 + \frac{\gamma + 1}{2} |\mathbf{x}_{pt}| \quad (4.7)$$

for nonlinear ray theory. Equation (4.7) follows from (3.4) and (4.2).

Before we close this section, we discuss a superficial relation between the nonlinear ray theory and shock ray theory. As discussed by Whitham (1959), the solution of an initial value problem of the equations (2.8)-(2.10) for small time  $t$  tend to the solution with the same initial values of the equations (2.8) and

$$\{G(M - 1)^2 e^{2(M-1)}\}_t = 0, \quad \{GV^2 e^{2(M-1)}\}_t = 0. \quad (4.8)$$

With a proper choice of  $\xi$  i.e. the initial value of the metric  $G$ , the first equation of (4.8) give  $G = (M - 1)^{-2}e^{-2(M-1)}$ . Therefore, it appears that for a small time the shock ray theory shock is governed by the equations of the nonlinear ray theory but this is only a superficial relation because it is the difference in the initial values in (3.5) for  $M_0(\xi)$  and (4.7) for  $m_0(\xi)$  which makes a nonlinear wavefront and a shock front to be distinct propagating curves. If we approximate  $(M - 1)^{-2}e^{-2(M-1)}$  by  $(M - 1)^{-2}$  for small  $M - 1$ , then it follows that initially, near the source of creation of the shock, the shock ray theory shock is governed approximately by GSD equations.

## 5 Piston problem when the shape of the piston is a wedge

Consider a wedge shaped piston which starts moving with velocity  $u_0 + u_1 t$  in the direction of the symmetry, assumed to be the direction of the  $x$ -axis. Let  $\xi$  be the distance along the piston measured from the vertex. Then for  $t > 0$  and  $u_0 > 0$

$$x_p(\xi, t) = \begin{cases} -\xi \sin \Theta_0 + (u_0 t + \frac{1}{2}u_1 t^2), & \xi > 0 \\ \xi \sin \Theta_0 + u_0 t + \frac{1}{2}u_1 t^2, & \xi < 0 \end{cases}, y_p(\xi, t) = \xi \cos \Theta_0, \quad (5.1)$$

For this piston motion, we get the following initial values for shock ray theory,

$$M_0(\xi) = 1 + \frac{\gamma + 1}{4}u_0 \cos \Theta_0, \quad V_0(\xi) = -\frac{(\gamma + 1)u_1 \cos \Theta_0}{4 \left\{ 1 + \frac{\gamma - 1}{2}u_0 \cos \Theta_0 \right\}}, \quad G_0(\xi) = 1 \quad (5.2)$$

The initial value for the nonlinear ray theory is

$$m_0(\xi) = 1 + \frac{\gamma + 1}{2}u_0 \cos \Theta_0 \quad (5.3)$$

In order that the relation (4.2) is satisfied, we need to choose a new  $\xi$  in (5.1), which we denote by  $\xi_{\text{new}}$  and is given by  $\xi_{\text{new}} = \xi / ((m_0 - 1)^{-2}e^{-2(m_0-1)})$ . Let us assume that this has been done for nonlinear ray theory.

### 5.1 Solution when the wedge shaped piston is concave to the flow ahead

It is easy to find the solution of (4.1)-(4.2) satisfying

$$m(\xi, 0) = m_0(\xi), \quad -\infty < \xi < \infty, \quad \theta(\xi, 0) = \begin{cases} -\Theta_0 & , \quad \xi > 0 \\ \Theta_0 & , \quad \xi < 0 \end{cases} \quad (5.4)$$

where  $0 < \Theta_0 < \pi/2$  (see expression (6.2.15) in Prasad 2001). Solving (4.3) we get the nonlinear wavefront with a pair of kinks joining three straight parts as shown in Fig. 5.1

and Fig. 5.2. Note that a kink is an image in  $(x, y)$ -plane of a shock in  $(\xi, t)$ -plane. We call the central part between the two kinks as 'disk', which is perpendicular to the axis of symmetry i.e. the  $x$ -axis. The outer straight parts, we call them 'wings', are parallel to the two sides of the wavefront at  $t = 0$ .

The initial value  $M_0$  for GSD is same as given in (5.2). However, to use the expression (4.4) for  $G(m)$ , we need to use a new  $\xi$  in (5.1) as in the case of nonlinear ray theory above. There is an exact solution of this problem also and the graph of the position of the GSD shock front is shown in Fig. 5.1 and Fig. 5.2. The general feature of a straight disc joined by two straight wings for a nonlinear wavefront is also present in a GSD shock at  $t > 0$ .

Since an exact solution of the equations of the shock ray theory and Euler's equations are not available, we compute the positions of shock ray theory shock numerically and compare them with positions of shocks by Euler solution and plot them in the same figures Fig. 5.1 and Fig. 5.2 (see comments on the computation of error in the position of the GSD and shock ray theory shock in the last but one paragraph in the introduction). We make following observations from Fig. 5.1 and Fig. 5.2.

(i) The shock fronts by shock ray theory and Euler solution are very close - almost undistinguishable at the times they have been shown.

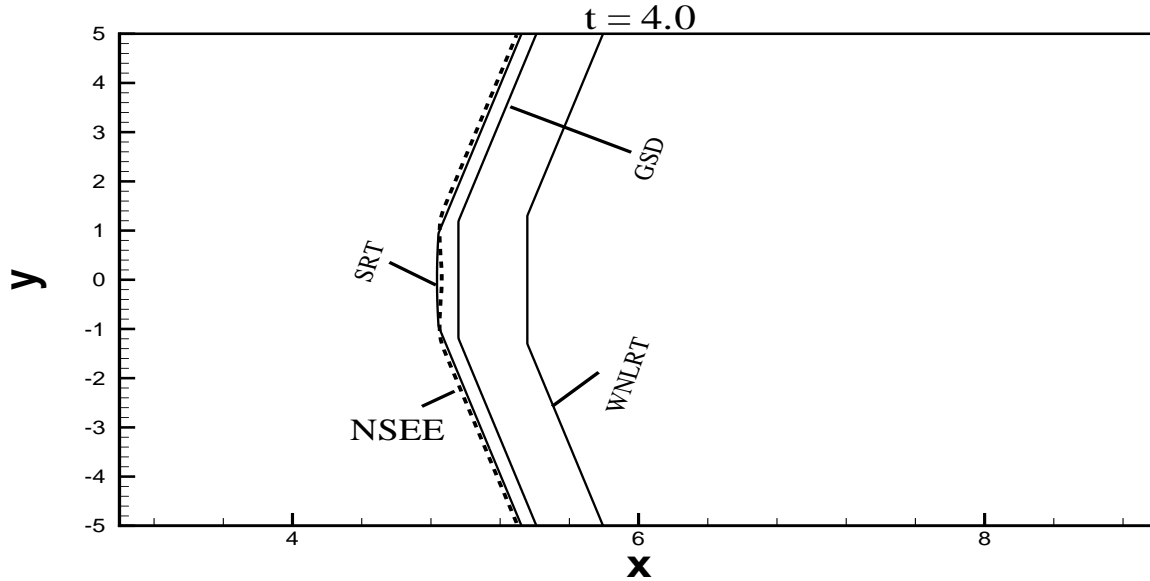

(ii) The results in Fig. 5.1 and Fig. 5.2 correspond to accelerating and decelerating pistons respectively. Initially the shocks and nonlinear wavefront start from the same position. However, since the GSD does not take into account the acceleration of the piston, in Fig. 5.1 the GSD shock starts falling behind the shock ray theory and Euler solution shocks which are pushed ahead by the acceleration of the piston. For an accelerating piston with  $u_1 = 0.15$ , the shock by GSD lags very much behind that by Euler solution at  $t = 6$ . In the case of a decelerating piston, the GSD shock is ahead of the piston as shown in Fig. 5.2, since the deceleration has effect on the Euler solution and shock ray theory shocks but not on the shock by GSD.

(iii) The difference between the positions of GSD and shock ray theory will rapidly increase in the case of a decelerating (accelerating) piston because the shock strength of the shock ray theory shock will decrease (increase) due to interaction of the shock with nonlinear waves of decreasing (increasing) amplitude coming from the piston at a later time (see the detailed results in Monica and Prasad 2001).

(iv) The nonlinear wavefront by nonlinear ray theory starts with a larger velocity compared to the shocks by the same piston motion and is always ahead of them. However, the piston acceleration will ultimately push the shock ray theory and Euler solution shocks so much that they will tend to catch up with the nonlinear wavefront, which is self-propagating i.e., it remains unaffected by the piston acceleration. When the piston is decelerating, the nonlinear wavefront by nonlinear ray theory has moved quite ahead of the shocks in Fig. 5.2 even at  $t = 4$  as compared to that in Fig. 5.1 at  $t = 6$ .

**Fig 5.1:** Comparison of results for a wedge shaped accelerating piston with  $\Theta_0 = 0.1178$ , initial velocity  $u_0 = 0.33$  and acceleration  $u_1 = 0.15$ . Here  $M_0 = 1.2$  and  $V_0 = -0.084375$ .

**Fig 5.2:** Comparison of results for a wedge shaped decelerating piston with  $\Theta_0 = 0.1178$ , initial velocity  $u_0 = 0.33$  and deceleration  $u_1 = -0.15$ . Here  $M_0 = 1.2$  and  $V_0 = 0.084375$ .

Successive positions of the shock front by shock ray theory have been shown in Fig. 5.3. The central disc of shock ray theory and Euler solution shock is convex when observed from the medium a head of it. This is a very interesting result and can not be observed in GSD shock (or the wavefront by nonlinear ray theory) when the initial shape is in the form of a concave wedge as considered here. If the initial shape was simply concave (but not a wedge) the central disc may become convex due to local divergence of rays in space not only for Euler solution (Sturtevant 1989) and shock ray theory but also for nonlinear ray theory (Prasad and Sangeeta 1999).

The results of this section for the concave piston problem show that shock ray theory

**Fig 5.3:** Successive positions of shock front using shock ray theory at a time interval 1. The shock is produced by a wedge shaped piston with  $\Theta_0 = 0.1178$ , initial velocity  $u_0 = 0.33$  and acceleration  $u_1 = 0.15$ . Here  $M_0 = 1.2$  and  $V_0 = -0.084375$ .

is an excellent theory to discuss this type of problems - not only there is a very good agreement with Euler solution but it reproduces a very important effect seen in the experiments.

## 5.2 Solution when the moving wedge shaped piston is convex to the flow ahead of it

### 5.2.1 Solution by WLNRT

Consider the initial data (5.4) with  $-\pi/2 < \Theta_0 < 0$  and  $\xi$  normalized suitably as mentioned after (5.3). The piston motion is given by (5.1) with  $-\pi/2 < \Theta_0 < 0$ . This would correspond to a moving wedge convex to the gas ahead of it.

In order to understand some interesting results, we need to reproduce here the Fig. 4 of Baskar and Prasad (2004) but with slight changed notations (see Fig 5.4). First, we define rarefaction curves  $R_1^-$  and  $R_2^+$  as the set of points in  $(m, \theta)$ -plane, which can be joined to  $(m_0, \Theta_0)$  through simple waves of the characteristic families

$$\frac{d\xi}{dt} = \mp \sqrt{\frac{m-1}{2g^2}} \quad (5.5)$$

of the equations (4.1)-(4.2). Then

$$R_1^-(m_0, \Theta_0) := \{(m, \theta) | \theta + \sqrt{8(m-1)} = \Theta_0 + \sqrt{8(m_0-1)}, 1 < m < m_0\}, \quad (5.6)$$

$$R_2^+(m_0, \Theta_0) := \{(m, \theta) | \theta - \sqrt{8(m-1)} = \Theta_0 - \sqrt{8(m_0-1)}, m_0 < m < \infty\}. \quad (5.7)$$

Similarly,  $S_1^+$  and  $S_2^-$  are the Hugoniot curves defined with the help of shocks of the first and second family respectively.  $(1, \Theta_0 + \theta_+^*)$  is a point where  $R_1^-$  meets the line  $m = 1$ ,

**Fig 5.4:** Rarefaction and Hugoniot curves in  $(m, \theta)$ -plane. Note  $\Theta_0 < 0$ .

where

$$\theta_+^* = \sqrt{8(m_0 - 1)} \quad (5.8)$$

and  $T$  is the  $R_2^+$  curve starting from  $(1, \Theta_0 + \theta_+^*)$  :

$$T : \{(m, \theta) | \theta - \sqrt{8(m - 1)} = \Theta_0 + \theta_+^*, 1 < m < \infty\}. \quad (5.9)$$

These curves lie on the boundaries of domains  $A$  and  $E$  in  $(m, \theta)$ -plane as shown in Fig. 5.4. For  $|\Theta_0|$  sufficiently small, it follows that  $(m_0, -\Theta_0) \in A$  and from the results in Baskar and Prasad (2004), it follows that the state  $P_r(m_0, -\Theta_0)$  on  $\xi > 0$  (subject to the restriction (5.11) below) can be joined to the state  $P_l(m_0, \Theta_0)$  on  $\xi < 0$  by the path  $P_l P_i P_r$ , where  $m_i$  is such that  $P_r$  lies on  $R_2^+(m_i, 0)$  (from symmetry it follows that  $\theta$  at  $P_i$  must be zero), where

$$\sqrt{8(m_i - 1)} = \sqrt{8(m_0 - 1)} - (-\Theta_0) = \sqrt{8(m_0 - 1)} + \Theta_0. \quad (5.10)$$

Therefore, the solution of (4.1)-(4.2) with initial data (5.4) (satisfying (5.11) below),  $\Theta_0 < 0$ , consists of a centered simple wave  $R_1$  of the first family and another centered simple wave  $R_2$  of the second family separated by a constant state  $(m_i, \theta = 0)$ . This is the case as long as  $-\Theta_0$  is not too large to make the right hand side of (5.10) negative. Therefore, if  $\Theta_0$  decreases, it attains a value  $\theta_c (< 0)$  such that the point  $P_r$ , while moving up in the Fig. 5.4 (actually the  $\theta = 0$  axis moves up), is on  $T$  for  $\Theta_0 = \theta_c$  and  $P_i$  is on the line  $m = 1$  where  $g = \infty$ . This means that the nonlinear ray theory is no longer valid. This leads to the conclusion that for a given value of  $m_0$ , the solution of the nonlinear

ray theory for a convex wedge moving in the gas at rest exists if and only if

$$\Theta_0 > \theta_c(m_0) = -\sqrt{8(m_0 - 1)} \quad \text{or} \quad |\Theta_0| < -\theta_c(m_0). \quad (5.11)$$

Using (5.3), we get  $-\Theta_0 < \sqrt{4(\gamma + 1)u_0 \cos \theta_0}$  which finally makes the condition (5.11) for the existence of solution to be

$$u_0 > \frac{\Theta_0^2}{4(\gamma + 1) \cos \Theta_0}. \quad (5.12)$$

When the solution of the nonlinear ray theory obtained in  $(\xi, t)$ -plane is mapped onto the  $(x, y)$ -plane by  $x_t = m \cos \theta$ ,  $y_t = m \sin \theta$ , we get the nonlinear wavefront consists of (see Fig. 5.5) two curved parts ED and BC (elementary shapes  $\mathcal{R}_1$  and  $\mathcal{R}_2$  as defined by Baskar and Prasad 2004) separating a straight disk CD (with  $m = m_i$ ,  $\theta = 0$ ) from two infinite straight wings BA and EF. As  $\Theta_0 \rightarrow \theta_c+$ ,  $m_i \rightarrow 1$ , and the eigenvalues (5.5) of (4.1) tend to zero. The relative displacement in  $(x, y)$ -plane of C from D in time  $\delta t$  is

$$g_i \delta \xi = g_i \left( 2 \sqrt{\frac{m_i - 1}{2g_i^2}} \delta t \right) = \sqrt{2(m_i - 1)} \delta t,$$

which tend to zero as  $m_i \rightarrow 1$ . At  $t = 0$ , the distance between C and D is zero, hence it follows that as  $\Theta_0 \rightarrow \theta_c+$ , the points C and D approach the  $x$ -axis so that the disk CD disappears. In this limiting case, the curved part of the nonlinear wavefront near the  $x$ -axis becomes almost a circle as if drawn by Huygens' method from the corner of the wedge. The central ray along the  $x$ -axis is a linear ray but all other rays, though nonlinear, are almost straight like linear rays but there is a nonlinear stretching, which is small for rays close to the  $x$ -axis and large for other rays (depending on the value of  $m_0$  and their location). We have shown two rays in the Fig. 5.5 for those cases for which  $m_i = 1.000375$  and  $m_i = 1.0001$ .

When  $-\Theta_0$  ( $< \pi/2$ ) is large and satisfies  $\Theta_0 < \theta_c(m_0)$ , the point  $P_r(m_0, -\Theta_0)$  lies above the line  $T$  and falls in the domain  $E$ . The solution of the nonlinear ray theory no longer exists. However, Fig. 5.4 still helps us to find the wavefront, which is partly linear and partly nonlinear. From  $P_r$  we move along the rarefaction curve of the second family up to the point  $P_i^*(1, \theta_i^*)$ , the rarefaction curve being  $R_2^+(1, \theta_i^*)$ . From  $P_i^*$ , we move along  $m = 1$  up to the point  $P_+^*$ , this corresponds to a linear wavefront. From  $P_+^*$ , we move along the rarefaction curve  $R_1^-(m_0, \Theta_0)$ .

$$\text{On } R_2^+(1, \theta_i^*) : \theta - \sqrt{8(m - 1)} = \theta_i^* = -\Theta_0 - \sqrt{8(m_0 - 1)}, \quad (5.13)$$

$$\text{On } R_1^-(m_0, \Theta_0) : \theta + \sqrt{8(m - 1)} = \Theta_0 + \sqrt{8(m_0 - 1)}. \quad (5.14)$$

Thus, on the nonlinear part of the wavefront  $\theta$  is a known function of  $m$  and we can numerically integrate the ray equations (4.3) with initial conditions on the piston at  $t = 0$ . This would give the nonlinear part of the wavefront. The linear part of the wavefront, which would be a circle with centre at the vertex of the wedge, can be obtained by Huygens' method. In the construction of this wavefront, we have avoided using  $g$ , which tends to infinity as  $m \rightarrow 1$ .

**Fig 5.5:** The nonlinear wavefront (shown by solid line)  $ABCDEF$  at  $t = 0.6134$  for  $m_0 = 1.13$ ,  $m_i = 1.05$  and  $\Theta_0 = \pi/8$ , consists of two curved parts  $BC$  and  $ED$  separating a disk  $BC$  from the two infinite wings. For the same  $\Theta_0$ ,  $m_0$  is so chosen that  $m_i = 1.0001$ , then the point  $C$  and  $D$  almost coincide (wavefront shown by long broken lines at  $t = 0.9927$ ) and the rays almost becomes straight as in the case of linear rays.

### 5.2.2 Condition for the existence of the solution by shock ray theory

Consider now the solution of the convex wedge problem moving along the  $x$ -axis by shock ray theory. The initial value can be formulated as in (5.1)-(5.2) where we shall take  $-\pi/2 < \Theta_0 < 0$ . As indicated at the end of the section 4, for a small time, the solution of the problem by shock ray theory will approximately be same as that obtained by a system neglecting the source terms in (2.9)-(2.10). In this case, the second equation of (4.8) for  $V$  decouples from the three equations (2.8) and the first equation of (4.8). These three equations are exactly the same as the equations of the nonlinear ray theory - the only difference is in relating the initial velocity  $u_0$  to the initial data for  $M_0(\xi)$  and  $m_0(\xi)$  as seen in the equations (5.2) and (5.3). Therefore, the critical value  $(-\Theta)_c = |\Theta_c|$  is given by (following (5.11))

$$|\Theta_c| = \sqrt{8(M_0 - 1)} \quad (5.15)$$

and the condition  $|\Theta_0| < |\Theta_c|$  for the existence of the solution, after using (5.2), gives

$$u_0 > \frac{\Theta_0^2}{2(\gamma + 1) \cos \Theta_0}, \quad (5.16)$$

where we note that the right hand side is positive for  $\Theta_0 < 0$ .

Once this condition has been satisfied, the solution of the convex wedge shaped piston problem by shock ray theory exists. The results obtained from the convex wedge shaped piston using shock ray theory will be similar to the results depicted in Fig. 6.3 to 6.7 where we have also plotted the results by Euler solution and GSD, when the angle between the normals of the two sides of the wedge =  $-2\Theta_0 = \pi/2$ . Note an important property from Fig. 5.5 that *all rays ultimately become parallel to the axis of symmetry, a result which is purely due to nonlinearity.*

## 6 Blast wave produced by an explosive placed in a container in the shape of a square

Let us assume that an explosion of a charge in a container produces a shock front which is initially a square and which has a uniform shock strength. Just behind this shock, we shall have a family of nonlinear wavefronts which are initially of the same shape and same uniform intensity  $w$ . For this problem, considering the symmetry in the shape of the piston, it is sufficient to set up an initial value problem for one half of the square (in fact a smaller part of square will do). In order to see the salient features of the shock front at  $t > 0$ , we first use nonlinear ray theory to trace the nonlinear wavefront, which was formed at  $t = 0$  at the piston. In this case, we can get an exact solution up to the time ( $t_{cnl}$ , see Fig. 6.1) of interaction of the disturbances from the corners on the same side.

Before we start further discussion, we first give the initial position of the square piston as

$$(x_p(\xi, 0), y_p(\xi, 0)) = \begin{cases} (0, y) & , \quad -0.5 < y < 0 \\ (x, 0) & , \quad -0.5 < x < 0 \\ (-0.5, y) & , \quad -0.5 < y < 0 \\ (x, -0.5) & , \quad -0.5 < x < 0 \end{cases} \quad (6.1)$$

The length of a side of the piston is 0.5.

We assume each side of the piston to suddenly start moving with a speed  $u_0$  and acceleration  $u_1 > 0$ .

### 6.1 Nonlinear ray theory solution.

The initial Mach number of the piston is given by  $m_0 = 1 + (\gamma + 1)u_0/2$ . The upper half of the piston, which we consider for setting up the initial value problem is a portion of the initial piston from  $P_1$  to  $P_5$  as shown in the inner square of Fig. 6.2. This results in the following initial value for the system (4.1)-(4.2)

$$m(\xi, 0) = m_0, \quad -\xi_0 < \xi < 3\xi_0, \quad \theta(\xi, 0) = \begin{cases} 0 & , \quad -\xi_0 < \xi < 0 \\ \pi/2 & , \quad 0 < \xi < 2\xi_0 \\ \pi & , \quad 2\xi_0 < \xi < 3\xi_0 \end{cases}, \quad (6.2)$$

**Fig 6.1:** When  $m > m_c$  and  $t < t_{cni}$ , the solution by nonlinear ray theory consists of a number of centered simple waves  $R_1, R_2, R_3, \dots$  separated by constant state regions  $C_1, C_3, C_5, \dots$

where  $\xi_0$  is chosen in such a way that when  $\xi$  varies in  $(-\xi_0, 0)$ , the point  $(x_p(\xi, 0), y_p(\xi, 0))$  moves on the line  $x = 0$  from  $P_1$  to  $P_2$ ; when  $\xi$  varies in  $(0, 2\xi_0)$  the point moves on the line  $y = 0$  from  $P_2$  to  $P_4$ ; and when  $\xi$  varies in  $(2\xi_0, 3\xi_0)$ , the point moves on the line  $x = -0.5$  from  $P_4$  to  $P_5$ . Then

$$\xi_0 = \frac{1}{4(m_0 - 1)^{-2} e^{-2(m_0 - 1)}} = \frac{1}{4g_0}. \quad (6.3)$$

If  $s$  is the arc length along the initial boundary measured from the point  $P_2$ , then  $\xi = 4\xi_0 s$ .

The condition (5.11) for the existence of the solution in terms of a critical angle  $\theta_c$  can also be written in terms of a critical Mach number  $m_c$ . Comparing the geometry of the wedge given by (5.1), we find the jump in the direction of the normal to be  $2\Theta_0 = \pi/2$ . Hence the critical Mach number is

$$m_c = 1 + \frac{\pi^2}{128} \quad (6.4)$$

and for  $m_0 > m_c$ , we have  $m_i > 1$ . Thus, a necessary and sufficient condition for the existence of the solution by the nonlinear ray theory is  $m > m_c$ . Considering the solution for small time by shock ray theory, the corresponding condition (5.15) can be written in terms of a critical Mach number  $M_c$  of the shock  $M_c = 1 + \pi^2/128$  and the solution of the shock ray theory equations exists only if  $M_0 > M_c$ . This critical Mach number can easily be translated in to a critical speed of the piston (see (5.16)).

When  $m > m_c$ , we can find an exact solution of the problem by nonlinear ray theory for  $t < t_{cnl}$ , where  $t_{cnl}$  is the time when the waves moving on the nonlinear wavefront from the two corners  $P_2$  and  $P_4$  meet. This in fact is the time when, starting from  $P_2$ , the leading end of the central simple wave of the positive characteristic family meet the line  $\xi = \xi_0$  in the  $(\xi, t)$ -plane (see Fig 6.1). For  $t < t_{cnl}$ , the solution in  $(\xi, t)$ -plane consists of isolated rarefaction waves  $R_1, R_2, R_3, \dots$  (of same strength) separated by constant states with same value of  $(m, \theta) = (m_i, \theta_i)$ , with  $m_i < m_0$  and from symmetry it follows that  $\theta_i = \pi/4, 3\pi/4, \dots$ . It is easy to determine an equation which would determine  $m_i$ .

For  $t > t_{cnl}$ , no exact solution of the problem can be found and we need to solve the problem numerically. Starting from  $t = t_{cnl}$ , the two rarefaction waves, say,  $R_2$  and  $R_3$  (of different families as shown in Fig. 6.1) start interacting. From the general theory in Baskar and Prasad (2004), it follows that these interactions will be of finite duration from time  $t_{cnl}$  to  $t_2$  leading again to two rarefaction waves of two different families from each interaction. Meanwhile, the newly generated rarefaction waves from interactions will bound the constant state regions between  $R_1$  and  $R_2$  etc., up to a time  $t_3$ . The solution beyond  $t_3$  will again consist of non-constant regions and constant state regions between the two rarefaction waves produced as a result of interaction of  $R_2$  and  $R_3$  etc. such as  $C_5$ .

Using the characteristic velocity (5.5) and (6.3), we find the value of  $t_{cnl}$  as

$$t_{cnl} = \frac{\xi_0}{\sqrt{\frac{m-1}{2g^2}}} = \frac{1}{\sqrt{8(m_0 - 1)}}. \quad (6.5)$$

For the initial velocity  $u_1$  of the piston to be 0.333 as taken in Fig. 6.3 to Fig. 6.7, we get  $m_0 = 1.4$  and therefore from (6.5), we have  $t_{cnl} = 0.55902$ . The shape of a weakly nonlinear wavefront, as it propagates, is similar to that of the shock front shown in Fig. 6.9, it was also observed nearly circular for  $t \geq t_{cnl}$ .

## 6.2 GSD Solutions

The main difference in nonlinear ray theory and GSD theory is that in the expressions (4.2) for the metric  $g$  and Mach number  $m$  are replaced by the expressions (4.4) and (2.2) for  $G$  and  $M$  respectively leading to corresponding changes in the expressions like (6.5). All qualitative features of the solution of nonlinear ray theory are also seen in the solution of GSD.

## 6.3 Interpretation of the initial conditions for the nonlinear ray theory, GSD and shock ray theory

The above features of the solutions by nonlinear ray theory and GSD will also be present in the solution by shock ray theory in a modified form. However, are these common features from all the three theories shared by the solution of the original problem i.e. by

**Fig 6.2:** *Piston motion: (a) sides of the square have fixed length and they simply move leaving 4 gaps  $P''_2 P'_2, P''_4 P'_4$  etc. (b) the lengths of all sides increase giving a bigger square  $P''_2 P''_4 P''_6 P''_8$ .*

Euler solution? This question becomes important because *there appears to be more than one initial data for Euler's equations which lead to the same initial value problem for any one of the three theories: nonlinear ray theory, GSD and shock ray theory.*

Consider the following two blast wave problems produced by a piston initially in the form of a square. The shapes of the piston for  $t > 0$  are shown in Fig. 6.2. (a) In the first problem, the lengths of the sides remain fixed as they move with same speed and at a later time  $t > 0$  we get a punctured square with gaps  $P''_2 P'_2, P''_4 P'_4, P''_6 P'_6, P''_8 P'_8$  at the corners. (b) The lengths of all sides increase as they move so that at a time  $t > 0$ , we get a bigger square  $P''_2 P''_4 P''_6 P''_8$ . We can have one more problem in which the corners of the expanding square are rounded as shown in the Fig. 6.2. All these problems lead to the same initial data for nonlinear ray theory or GSD or shock ray theory but for Euler solution we need to prescribe different boundary conditions. In the problem (a), a vacuum is created in the gap and suitable boundary conditions are to be provided for Euler's equations. Similarly, in the case of (b), the fluid at the corners is continuously pushed and a different type of boundary conditions are required. The two problems (a) and (b) have different Euler solutions, but the corresponding problem either for nonlinear ray theory or GSD or shock ray theory has same solution.

The nonlinear ray theory shows that from the corner  $P_2$ , we have two elementary shapes (images of elementary waves) corresponding to  $R_1$  and  $R_2$  elementary waves. They are separated by a straight part carrying the value  $m_i$  (i.e. a perturbation amplitude  $w_i$  given by  $w_i = 2(m_i - 1)/(\gamma + 1)$ , see the relation (4.2)) and have normal direction given by  $\theta_i = \pi/4$ . What should be the correct boundary condition at the piston for the Euler's equations corresponding to this solution of nonlinear ray theory? We note that nonlinear ray theory is valid for small  $m - 1$  but there is a critical value  $m_c$  (slightly greater than 1, as seen from (6.4)) which is the lowest value of  $m_0$  and for this  $m_i = 1$  or  $w_i = 0$ . For some admissible values of  $m_0$  (see Table 6.1) and for  $\Theta_0 = \pi/4$ , we find

that the values of  $m_i - 1$  are quite small.

**Table 6.1:**  $\Theta_0 = \pi/4$

$m_0$	1.1	1.15	1.2	1.25
$m_i$	1.001486	1.012016	1.028742	1.049426

Thus, the values of  $m_i$  obtained in nonlinear ray theory correspond to still smaller piston speed at the corner. Moreover, for a small piston speed, the boundary conditions for Euler solution is applied on the piston fixed at its initial position. Hence, we think that the most appropriate boundary value at  $P_2$  (and hence at other corners) is zero velocity of the fluid (and hence the piston). Since the domain in the  $(\xi, t)$  - plane just opposite to  $P_2$  is  $C_2$  (see Fig. 6.1), where the solution is constant, the most appropriate value of the acceleration at  $P_2$  should also be zero. At all other points we can prescribe the initial fluid speed  $1 + w$  which is the same as the initial piston speed  $|(x_{pt}(\xi, 0), y_{pt}(\xi, 0))|$ .

From the general theory on the Riemann problem for kinematical conservation laws (Baskar and Prasad 2004), it follows that  $m_i$  in the region  $C_2$  in Fig 6.1 satisfies  $m_i < m_0$ . Similarly from the result on interaction of two centered waves in the same paper, the value  $m_{ii}$  in  $C_5$  satisfies  $m_{ii} < m_i$ . Hence, after the two centered waves from the corners of the square have completed interaction, the Mach number  $m_{ii}$  directly above the side  $P_2P_4$  is smaller than anywhere else. Hence, the nonlinear wavefront opposite to the corners now move faster than that directly opposite to the sides of the square. This very clearly explains the reason of the evolution towards a circular shock (discussed at the end of this section).

## 6.4 Comparison of the Euler solution and solutions by GSD and shock ray theory

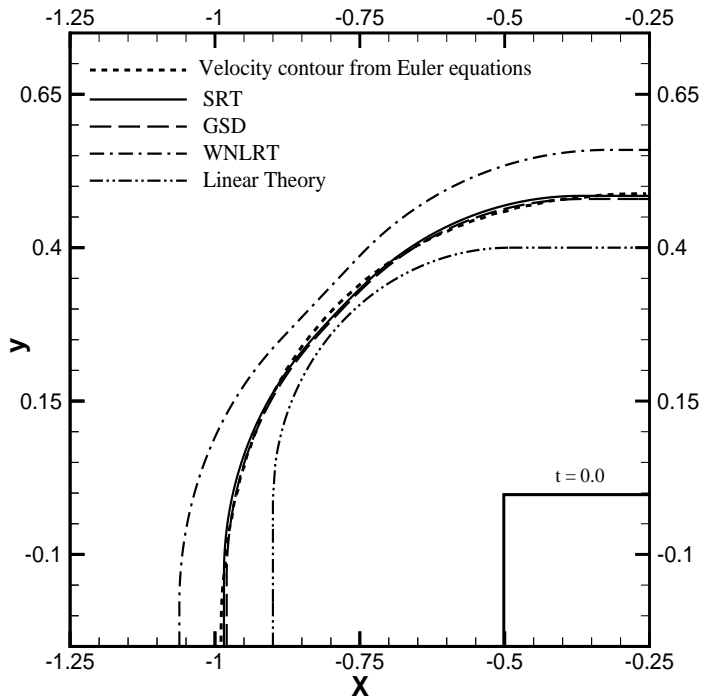

As discussed above, we apply the appropriate boundary conditions for Euler solution on the initial position of the square piston and solve the Euler's equations. Given the piston motion, we can set up the initial values for the equations of shock ray theory from (3.5) and (3.12). For shock ray theory we take  $\xi$  to be the arc length from  $P_2$  and hence  $G_0 = G(\xi, 0) = 1$ .

Before we discuss a comparison of the results, we calculate  $t_{cs}$ , the time when the waves from the corners  $P_2$  and  $P_4$  (Fig. 6.2) meet at a point above  $P_3$  according to shock ray theory. The relevant eigenvalue (or characteristic velocity) of the system (2.5)-(2.6) is  $\sqrt{(M - 1)/(2G^2)}$  in  $(\xi, t)$ -plane. Since the wave from  $P_2$  moves into the constant state with  $M = M_0$  and  $G_0 = 1$ , it reaches  $\xi = 1/4$  i.e., a point above the point  $P_3$  in time

$$t_{cs} = \frac{1}{\sqrt{8(M_0 - 1)}}. \tag{6.6}$$

Since  $0 < M_0 - 1 < m_0 - 1$ , it follows from (6.5) and (6.6) that

$$t_{cnl} < t_{cs}. \tag{6.7}$$

**Fig 6.3:** Comparison of results at time  $t = 0.4$  in the case of a blast wave with an accelerating piston with initial velocity  $u_0 = 0.333$  and acceleration  $u_1 = 0.5$ .

**Fig 6.4:** Comparison of results at time  $t = 0.8$  in the case of a blast wave with an accelerating piston with initial velocity  $u_0 = 0.333$  and acceleration  $u_1 = 0.5$ .

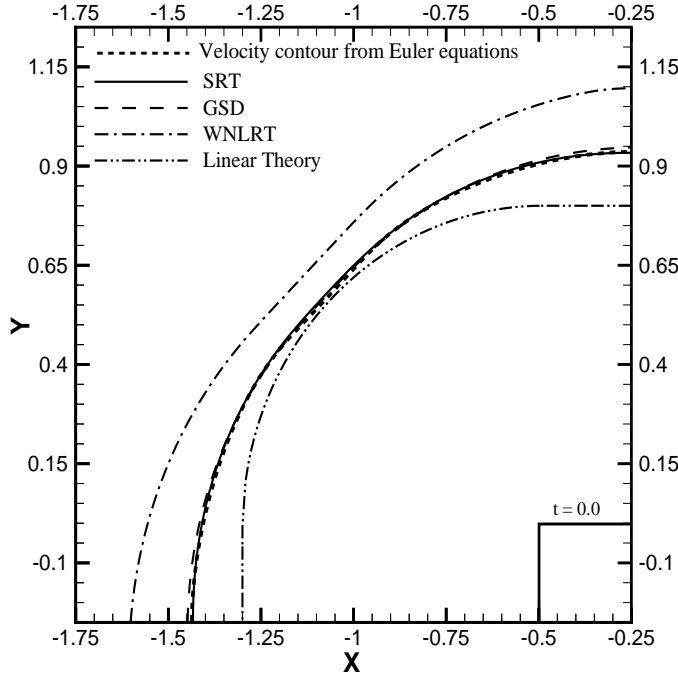

**Fig 6.5:** A long time comparison of results at time  $t = 1.6$  in the case of an accelerating piston with initial velocity  $u_0 = 0.333$  and acceleration  $u_1 = 0.5$ .

**Fig 6.6:** Comparison of results at time  $t = 0.4$  in the case of a blast wave with a deceleration piston with initial velocity  $u_0 = 0.333$  and deceleration  $u_1 = -0.5$ .

**Fig 6.7:** Comparison of results at time  $t = 0.8$  in the case of a decelerating piston with initial velocity  $u_0 = 0.333$  and deceleration  $u_1 = -0.5$ .

For the value  $M_0 = 1.2$ , we find  $t_{cs} = 0.79057$ . This gives an order of time when we may consider the shock front to be approximately circular. We shall comment on this later in this section.

Fig 6.3 - Fig 6.7 contain graphical depiction of the results by all five theories mentioned in this paper. Though we have drawn the graphs of results by the nonlinear ray theory and linear theory also, the important comparison is between the results by shock ray theory, GSD and Euler solution. Fig. 6.3 - Fig. 6.5 contain results for an accelerating piston at time  $t = 0.4$ ,  $t = 0.8$  and  $t = 1.6$  respectively. All three shocks start with same initial position and same initial velocity and hence for small  $t$ , they almost overlap. At time  $t = 0.4$ , Fig 6.3 shows that all three curves representing the results by the three theories almost overlap but the shock ray theory curve occupies over all a middle position of the GSD and Euler solution curve. At  $t = 0.8$  (Fig 6.4), the shock ray theory and Euler solution overlap as at  $t = 0.4$  but the GSD curve now lags behind and this effect becomes more pronounced at  $t = 1.6$  (Fig. 6.5). For an accelerating piston, energy is fed into the flow at an increasing rate but this increasing input of the energy is not taken into account by GSD. This causes the GSD shock to lag behind. We stopped the comparison at  $t = 1.6$  as there is not much reason to continue solution beyond this time because as  $t$  increases GSD result is bound to differ significantly from that of shock ray theory. Fig. 6.6 and Fig. 6.7 contain results of a decelerating piston at  $t = 0.4$  and  $t = 0.8$  respectively. At both times, all three results are very close but the shock ray theory curve lies almost in the middle of the other two curves. In the decelerating piston case, the energy is fed into the flow at a decreasing rate. Till the time we have presented our results, the deceleration has not sufficiently affected the relative positions of shocks

and this has caused GSD shock to be only little ahead of the shock ray theory and Euler solution shocks. It is well known that GSD does give good result in some cases (see Whitham 1974) but it is only accidental (Prasad, et al. 1991). What is important for us is to note that shock ray theory gives consistently good result, very close to Euler's solutions not only in this case but also for the wedge shaped piston problem discussed in the previous section (Fig. 5.1 and Fig. 5.2). This agrees with the conclusion of Kevlahan (1996), who compared the results of the shock ray theory with Euler solution and found an excellent agreement between the two results. He also found excellent agreement of the results of shock ray theory with experimental results of Sturtevant and Kulkarni (1976) and some known exact solutions.

## 6.5 Evolution toward a circular shock

We now discuss the second aim of this paper. The shock front (more precisely the linear wavefront) produced by a square piston, when calculated according to the linear theory will tend to a circle as  $t \rightarrow \infty$ . At any finite time, it will have four straight parts (obtained easily by using the linear ray theory) joined by circular arcs (arising from corners and obtained by Huygens' method) as shown in the Fig. 6.8. If  $a$  is the length of the side of the square at  $t = 0$ , the ratio of total length of the straight parts of the linear wavefront to that of the circular arcs is  $2a/(\pi t)$ . Here  $a = 0.5$  and, therefore, at  $t = 0.8$ , this ratio in Fig. 6.8 is approximately  $1/3$ . The linear wavefront may be treated as almost circular, when this ratio is  $1/10$  i.e  $t = O(20a/\pi)$  which is equal to  $\approx 3$ . Fig. 6.9 shows the successive positions of the shock ray theory shock up to a time  $0.79057$  which is quite close to  $t_c$ . At this time, a circle (shown by the symbol "X") has been drawn with its center at the center of the square. The shock and the circle are almost coincident. Whereas, the Fig. 6.8 shows that the linear wavefront deviates very much from an appropriate circle. This evolution almost into a circle of an initially square shock has taken place at  $t_c$  which is just  $1/3$  of the time when the linear wavefront may be treated as a circle. The reason for the shock to tend to become a circle are the nonlinear waves on the shock, which move with the characteristic velocities (or eigenvalues) of the hyperbolic system (2.5)-(2.6). This tendency for a convex shock front to become smooth is nothing but corrugation stability of a plane shock front (Monica and Prasad 2001) and is clearly explained in the end of the section 7. The interaction of nonlinear waves on the shock front, as noted while discussing the results of nonlinear ray theory in Fig. 6.1, plays an important role.

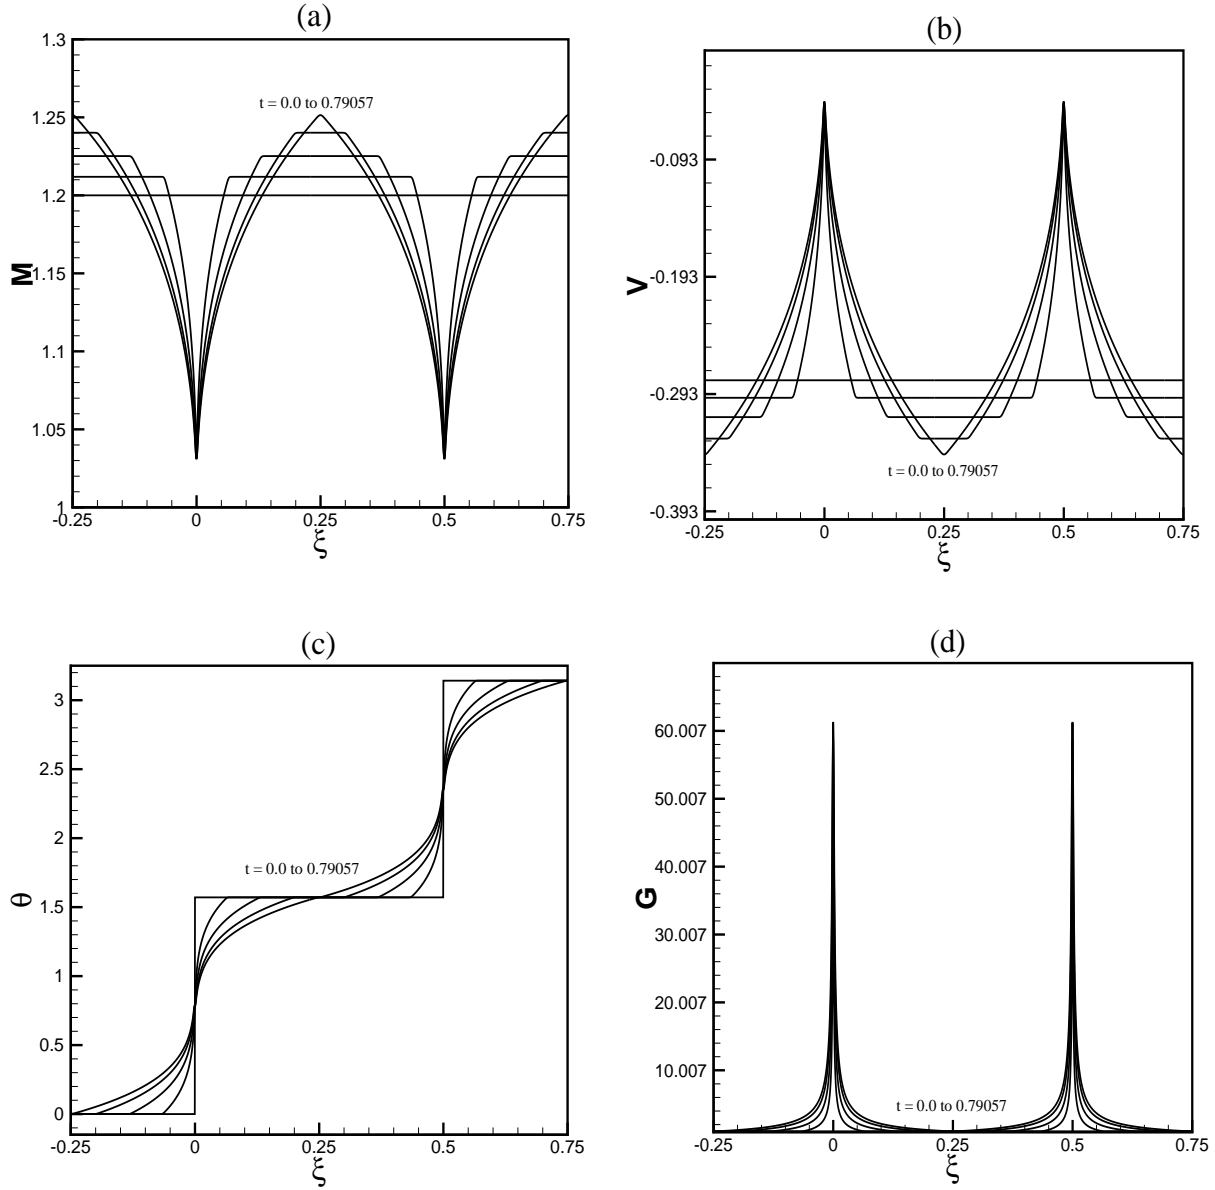

Some characteristic properties of the shock produced by a square piston have been shown graphically in Fig. 6.10 and Fig. 6.11. Fig. 6.10 does not give a good resolution of a very small constant state regions at the original four corners, which has been shown by a graph of  $\Theta$  with  $\xi$  in a small neighbourhood of  $\xi = 0$  in Fig. 6.11. This corresponds to the constant state region  $C_2(m_i, \pi/4)$  in Fig 6.1. Fig 6.10d shows that the value of  $G$  is very large in a small neighbourhood of  $\xi = 0$ , which implies that a very small neighbourhood of  $\xi = 0$  where  $\Theta$  is constant gets mapped onto a straight part of the shock as seen in Fig. 6.9, where the shock front deviates a little from the circle.

**Fig 6.8:** Successive positions at times  $t$  of a leading wavefront from a blast wave due to a square shaped source using linear theory. A circle (shown by the symbol 'X') of an appropriate radius and centre at the centre of the square has been compared with the linear wavefront at  $t=0.8$ .

**Fig 6.9:** Successive positions of a leading shock front (at different times  $t$ ) from a blast wave due to a square shaped source using shock ray theory with  $u_0 = 0.333$ ,  $u_1 = 0.5$ . A circle of an appropriate radius and centre at the centre of the square has been shown to compare with the shock front at  $t = t_c$  by the symbol 'X'. Here  $M_0 = 1.2$  and  $V_0 = -0.28125$ .

**Fig 6.10:** Variation in  $M$ ,  $N$ ,  $G$  and  $\theta$  with respect to  $\xi$  in the case of a blast wave from a square shaped source using shock ray theory. Inner most curves correspond to the results at  $t = 0$  and outermost ones to those at  $t = 0.79057$ . Here  $u_0 = 0.333$  and  $u_1 = 0.5$ .

Fig 6.11: An enlarged  $\theta$  graph presented in Fig 6.10(c).

## 7 Shock produced by a wavy piston

Interesting results on the propagation of a shock initially in a periodic shape have been discussed by Monica and Prasad (2001). In this paper, we shall present numerical results for only two cases but before we do that we give an extension of the result (6.4). In fact, this extension is rewriting the result (5.15) in terms of the critical Mach number  $m_c$  as explained for (6.4). Consider the initial position of a nonlinear wavefront, which consists of two infinite straight parts meeting at a point. Let  $(m, \theta)$  on the lower part be  $(m_0, 0)$  and that on the upper part be  $(m_0, \theta_r)$  with  $0 < \theta_r < \pi$ . The extension of the result (6.4) is the existence of a critical number  $m_c$ :

$$m_c(\theta_r) = 1 + \frac{\theta_r^2}{32}, \quad (7.1)$$

such that if  $m_0 > m_c$ , the solution of the Riemann problem for equations (4.1)-(4.2) with initial condition  $(m, \theta) = (m_0, 0)$  for  $\xi < 0$  and  $= (m_0, \theta_r)$  for  $\xi > 0$  exists and is unique.  $m_c$  increases monotonically from 1 to  $1 + \pi^2/32 = 1.3084$  as  $\theta$  varies from 0 to  $\pi$ .

Consider now a piston whose shape is in the form of a periodic curve which is formed by periodically extending in  $y$ -direction a finite wedge given by

$$x = \begin{cases} x_0 + y \tan \Theta_0, & -x_0 \cot \Theta_0 < y < 0 \\ x_0 - y \tan \Theta_0, & 0 < y < x_0 \cot \Theta_0 \end{cases}, \quad (7.2)$$

where  $\Theta_0$ , a constant satisfying  $0 < \Theta_0 < \pi/2$ , is the angle which the normal to the upper part of the wedge makes with the  $x$ -axis. We choose  $\xi$  to be the arc length along

the piston measured from the corner  $(x_0, 0)$  of the piston. Then, the corners of the piston above  $(x_0, 0)$  in one period are at  $(0, x_0 \cot \Theta_0)$  and  $(x_0, 2x_0 \cot \Theta_0)$  and correspond to  $\xi = x_0(1 + \cot^2 \Theta_0)^{1/2} = \xi_1$  say, and  $\xi = 2\xi_1 = \xi_2$  say. Similarly the corners of the piston below  $(x_0, 0)$  in the lower period are at  $(0, -x_0 \cot \Theta_0)$  and  $(x_0, -2x_0 \cot \Theta_0)$  and correspond to  $-\xi_1$  and  $\xi_2$ .

The shock front, produced by the piston, will initially coincide with the piston so that the change in the angle of the normal at the corner  $(x_0, 0)$  is  $2\Theta_0$ . Therefore, the value of  $M_0$ , the constant Mach number of the shock given by (3.5) should (following (7.1)) satisfy  $M_0 > 1 + \Theta_0^2/8$  for the existence of the solution.

**Fig 7.1:** Successive positions of a shock, produced by an accelerating piston of periodic shape, using shock ray theory with  $u_0 = 0.333$  and  $u_1 = 0.5$ .

**Fig 7.2:** Comparison of results in the case of a periodic shock front with  $u_0 = 0.333$  and  $u_1 = 0.5$ .

The angle  $\Theta$  between the normal to the shock front and the  $x$ -axis is initially given by

$$\Theta(\xi, 0) = \begin{cases} \Theta_0 & , \quad \text{if } -\xi_2 < \xi \leq -\xi_1 \\ -\Theta_0 & , \quad \text{if } -\xi_1 < \xi \leq 0 \\ \Theta_0 & , \quad \text{if } 0 < \xi \leq \xi_1 \\ -\Theta_0 & , \quad \text{if } \xi_1 < \xi \leq \xi_2 \end{cases} \quad (7.3)$$

and periodically extended for  $\xi < -\xi_2$  and  $\xi > \xi_2$ . The above initial condition corresponds to three Riemann problems in the intervals: 1.  $(-\xi_2, -\xi_1)$  and  $(-\xi_1, 0)$ ; 2.  $(-\xi_1, 0)$  and  $(0, \xi_1)$ ; 3.  $(0, \xi_1)$  and  $(\xi_1, \xi_2)$ . The solution of the nonhomogeneous system (2.8)-(2.10) for a small time approximates the solution of the corresponding system of four conservation laws (2.8) and (4.8). To the reduced system, analysis of Baskar and Prasad (2004) of the Riemann problem for the kinematical conservation laws (presented in the first part of the section 5.2 in this paper) would apply. Later on, the centered waves, which emerge out of the reduced equations as shown in Fig. 6.1, would get modified by the source terms and waves from other periods would come and interact. This would result in corrugational stability leading to the formation of a smooth shock front at a large time (Monica and Prasad 2001). From the corners in the center of the convex parts (such as that at  $\xi = 0$ ) two centred rarefaction waves would emerge. Similarly, from the corners in the concave parts (such as those at  $-\xi_1$  and  $\xi_1$ ), two shocks emerge. Later on they will go through multiple interactions leading to a series of complex shapes of the shock front as the time  $t$  increases, see Fig. 7.1.

In Fig. 7.2, we have shown the comparison between the GSD, shock ray theory and the nonlinear ray theory. As observed in the previous cases for an accelerating piston, the shock front from GSD remains behind the shock ray theory shock and the wavefront from nonlinear ray theory travels ahead of it. From the comparison of results with Euler equations of the previous sections, we argue that Euler solution and shock ray theory would be close. Therefore, although qualitatively the shape of the shock front from GSD is same, the shock position remains behind the shock from shock ray theory and therefore from full gas dynamics equations. It is also observed (in the numerical solution not presented here) that when we increase the acceleration of the piston, the shock front from shock ray theory comes closer to the wavefront obtained from nonlinear ray theory and hence travels much ahead of GSD. Finally, after a long time, the effect of acceleration of the piston will dominate and the shock ray theory and Euler solution shocks would move far ahead of the GSD shock and the nonlinear ray theory wavefront.

## Conclusion

We have derived a new set of conservation forms of the first two compatibility conditions of shock ray theory for a weak shock. These conservation forms are more natural and follow a pattern which can be easily extended for each one of the infinite set of compatibility conditions for a weak shock. Hence it is possible to write conservation form of higher order shock ray theory with three or more compatibility conditions. We have carried out intensive numerical calculation and found that:

(i) Shock ray theory gives results which agrees very well with Euler solution results compared to the agreement of the results of GSD.

(ii) The results of shock ray theory show that nonlinear waves on the shock front help a non-circular shock to evolve into a circular one quite rapidly.

(iii) We theoretically show that there are limitations on the applicability of nonlinear ray theory, GSD and shock ray theory to a piston problem when the piston has a corner making an obtuse angle to the flow: it may move with a small velocity to produce a weak shock but its velocity should not be too small when the angle of the wedge is fixed.

(iv) The difference in the solution of GSD and Euler solution may become more significant for a strong shock with larger values of  $V$ . The shock ray theory for a strong shock has been just formulated with just two compatibility conditions (Prasad 2004) and we hope that the new formulation would lead to equations, which also give good results.

The comparison and limitations discussed in this paper are very important. GSD and shock ray theory with kinematical conservation laws are now very powerful theories to solve many practical problems and they also take considerably less time compared to Euler solution. As mentioned in the introduction, attempts have been made to discuss some finer limiting results of the shape of a shock front by GSD, Apazidis et al. (2002). Such results are acceptable only if it can be shown that the error between the GSD results and the solution (not numerical but exact) of the Euler's equations are much smaller than those involved in the finer structures. What we see from the comparison of the results that GSD will certainly fail in reproducing almost all limiting results. One may use shock ray theory with caution or probably use a higher order shock ray theory.
